HOW TO STUDY ANATOMY.*

BY STEPHEN SMITH, M.D., LL D.,
NEW YORK.

AN accurate and practical knowledge of the mechanism of the human body lies at the foundation of true success in the pursuit of the profession of medicine. It is of the utmost importance, therefore, that you should at the outset adopt a plan of study which, while it fascinates, and thus absorbs all your attention, tends also powerfully to fix firmly in your memory the associated relations of function and structure. It is only when these relations are so thoroughly grasped and retained by the mind that structure at once suggests function, and function suggests structure, that anatomy is made available in all the emergencies of the daily practice of medicine and surgery.

It cannot be denied that the present method of studying anatomy does not, as a rule, accomplish this result. How rarely does a student become so interested in the study of anatomy that in his zeal in its pursuit he neglects his other studies, or sacrifices pleasures and amusements? And, what is more important, how seldom do we meet a practitioner who can readily recall the precise anatomy and functions of even the more important organs and structures of the body? If we examine critically the modern textbooks on anatomy, for the purpose of determining their adaptation to the two-fold purpose of inspiring the student with a genuine love of the science and of rendering his knowledge instantly available in practice, we shall be convinced that they accomplish neither result; nor is it difficult to explain the cause of failure. The course of study is entirely wanting in that system, or orderly and logical development of the structures of the body, which appeals to the inventive and constructive faculties. Instead of being treated as an entity, in which each organ and structure contributes in due proportion to the completed apparatus, the several parts are studied in a fragmentary and disconnected manner, which necessarily fails to interest even the most inventive genius. The fact is entirely lost sight of that anatomy is a natural science, and that, like all natural sciences, it has a perfectly logical development, which, when properly unfolded, leads the mind insensibly from the study of simple parts to their arrangement into complex forms, as is abundantly illustrated in the science of botany, or chemistry, or biology. But neither textbooks on anatomy nor teachers of this fundamental branch of a medical education adopt the natural system of teaching this science. On the contrary, the scheme of study is so arranged as to prevent associated relations, and hence continuity of thought, on the part of the student. Therefore, he is constantly required to memorize abstract facts having no necessary connection with each other. Take, for example, the experience of a medical student in attendance at one of our most advanced medical colleges during the last year: He states that his first lesson in anatomy was a description of the external parts of the clavicle; the second was a similar description of the scapula; the third was a similar study of the femur. Meantime he had learned nothing of the structure of bones, nor of their purposes in the skeleton. When questioned he was found to be impressed with the belief that his success as a student depended solely upon his ability to retain and promptly repeat the terms which he found in his textbook. The wonderful organism which he was studying had no more attractions for him than would a language to a student who, in learning it, was required first to commit its dictionary to memory. The prevalent method of pursuing anatomy might be compared to the study of a cotton mill, by beginning with a spindle and learning all of its parts, then examining a distant wheel and committing to memory every minute detail of its construction, next learning all the peculiar names of a section of its frame-work, and thus proceeding until the entire machine had been studied in detached fragments. It is evident that no student would become thoroughly interested in such a study, nor would his knowledge of the machinery make him an expert engineer. He might be able to answer every question involving mere book-terms and yet have very little useful or usable information if he were called upon to remedy defects in its machinery.

But an experience of many years in teaching anatomy convinced me that a course of study may be followed which will thoroughly interest the average student from the first, and enable him readily to acquire, and firmly to retain in his memory the minutest details of function and structure of tissues. How then should anatomy be studied? I answer, precisely as you would begin, continue, and finish the study of any other mechanism with the structure and functions of which you wished to become as familiar as was the inventor. It is evident that to obtain such accurate knowledge of any machine you must study it along the lines pursued by the inventor in the development of its several parts. This would require that you should place yourselves in such relations to him as to think his thoughts from his first conception of the needs of such an apparatus or organism to its completion in the perfected instrument. And herein lies the charm and fascination in the study of anatomy if you adopt that logical method which the inventor pursues in the creation of a machine. From the very beginning of your studies you would be led to think the thoughts of the Creator, and as the wonderful mechanism of the human body was gradually unfolded, you would become more and more inspired with the loftiest conceptions of the Divine wisdom and power. The Psalmist, in contemplating the evidence of design in creation, sang, "How pleasant unto me are Thy thoughts, O God; how great is the sum of them?"

It cannot be doubted that the best instructor of a person who is about to study a machine so thoroughly that he can become its engineer would be the inventor himself, for while describing his own work he would naturally become very enthusiastic and

*An address delivered to the students of the Medical Department of the Syracuse University, October 13, 1902.

give the most accurate and detailed account of the inception, development and completion of his invention. As the student followed the train of thought, he would catch the inspiration of the inventor, and as each new feature of the structure gradually developed in orderly and logical succession, his mind would be aglow with the enthusiasm of his teacher, and he would be insensibly transformed into an inventor, architect, creator, and, quite unconsciously, the thing studied would become his own. Such a scheme would lead the student to begin with the inventor's first conception of the machine about to be invented. That conception is always preceded by a recognition of a function to be performed, and the absence of any apparatus or organism to perform it. In other words, the universal law governing inventions requires that the function to be performed must first be recognized before the structure is devised. The history of every invention shows that it grew out of a recognized need of a machine to accomplish a given object, and that in its construction each part was so devised that while it performed a special function of its own it contributed a force or factor to the completed mechanism necessary to the successful performance of its grand purpose. We may, and should, apply the same method to the study of the structure of the human body. We should first recognize fully the function to be performed before we undertake to construct the apparatus adapted to its performance. Herein lies the secret of the successful invention of every useful mechanism. The student who enters upon and steadily pursues the study of anatomy in this spirit is from the first an inventor, and is constantly recognizing functions to be performed, and is as constantly bending all his energies to devise structural appliances to perform those functions. He not only enters into the thoughts of the Creator, but he becomes himself a creator. Thus a genuine inspiration stimulates every inventive faculty of his mind, and instead of being a mere passive agent, receiving and storing away in his memory dry and often worthless technical terms, he becomes an aggressive inquirer and explorer in this new field of science.

Now, a course of study of anatomy so arranged that the student is from the first brought into such immediate relations with the Creator of the human mechanism that he will think His thoughts, presupposes that the Creator entered upon, proceeded with, and concluded his work according to the methods which govern all inventions. That is, the Creator discovered a want in creation; a function unperformed, and forthwith proceeded to invent an instrument to meet that want and perform that function. In adopting this theory we must assume the direct creation of man as a new and original creature, specifically adapted in every structure for a given purpose, and our study must be along the lines already indicated, viz.: First of all learn the function to be performed by this new creation and then follow the development of structure to its completion in the perfected organism.

The criticism which will be made upon this scheme of study is evident. It will be alleged that we ignore the modern theory of evolution, and thus inculcate antiquated ideas in regard to creation which are liable to mislead the student. In defence of the method it may be said that the same result can be reached by adhering to the doctrine of evolution, but the scheme would necessarily be intricate and involved to such an extent as to be confusing to the average medical student. Besides, the terms of creation are used because they are more suggestive of the facts of anatomy than any other terms that may be devised. Perhaps the most important testimony in favor of this method of teaching anatomy is that given by Professor Huxley, the greatest advocate of the theory of evolution. In one of his later lectures, describing the process of development of an ovum as the several stages are seen to succeed each other in symmetrical order under a powerful microscope, he is reported as saying:

"Strange possibilities lie dormant in that semi-fluid globe. Let a moderate supply of warmth reach its watery cradle and the plastic matter undergoes changes so rapid, and yet so steady and purpose-like in their succession that we can only compare them to those operated by a skilled operator on a formless lump of clay. We see, as it were, a skilled modeller shaping the plastic mass with a trowel; as if a delicate finger traced out the line to be occupied by the spinal column and molded the contour of the body, pinching up the head at one end and the tail at the other, and fashioning flank and limb into the salamandrine proportions in so artistic a way that, after watching the process hour by hour, one is almost involuntarily possessed by the notion that some more subtile aid to vision than an achromatic would show the hidden artist with his plan before him, striving with skilful manipulation to perfect his work."

A very distinguished writer refers to this quotation as follows:

"The above are Huxley's own words. That is to say that the first biologist in Europe (according to Virchow), when he comes to describe the development of life, can only do so in *terms of creation*."

With these explanatory remarks, I propose to develop the outlines of a course of study of anatomy based on the "Terms of Creation." If we approach the subject as inventors, and that is the true spirit in which we entered upon this study, our first inquiry would be as to the origin of the conception that man should be created. That is, what were the conditions existing which required the creation of man? We might, perhaps, arrive at a correct conclusion if we analyzed his existing organism, but, as in the Bible narrative, there is a statement of the immediate cause of his creation, and as this is the only record of the kind in human history, and answers our purpose, we will adopt it.

Referring then to the account of creation as given in Genesis, we learn that the earth had been prepared for living things, and in an orderly manner there had appeared grass, the herb, the fruit tree, living creatures in the waters, winged fowls, cattle and creeping things and beasts of the earth, and the Creator pronounced everything good. But now there seems to have been a pause in creation, and, as we follow the narrative, we learn it was discovered that there "was not a man to till the ground" or "replenish the earth and subdue it" or "have dominion" over it. Here was a new incentive to creative energy, and apparently a more difficult task was never presented even to Omnipotence. The conclusion of the deliberations of the Council of Creation are given in the announcement: "Let us make man in our image, after our likeness." This is the first recorded mention of man in the history of the earth. The decision is in the language of a council of architects, inventors, or creators. As students, we are at once interested in determining how this man was made in the image and likeness of the Creator. On examining the record we learn only that the Creator "formed man of the dust of the ground, and breathed into his nostrils the breath of life." No details are given of the method of procedure in constructing the human body, and we are left to determine these facts by our knowledge of the laws governing the invention and construction of machinery, and an analytical and synthetical study of the completed organism as we have it before us. That is, we

must place ourselves as nearly as possible in line with the logical thoughts of the Inventor, and thus have the machine develop in our own studies as it did in His.

In regard to the laws of invention we have stated that the first conception in the inventors mind is function, the second structure. Having recognized the former, we are now to devise and create a structure adapted to perform that function. What rule shall be our guide? Evidently the rules governing construction in all inventions. These rules may be stated as follows: Every inventor creates, first, the frame-work; second, the apparatus which operates it; third, the motor power or force which gives the apparatus energy or activity; fourth, the mechanism by which the life and the integrity of the organism is to be maintained; fifth, the organs by which the machine, as a whole, is to be reproduced.

Following the order of invention, we must determine what is the framework of the body and begin construction with it. It is evident, on a general survey of the several tissues of the human organism, that the articulated bones make its frame-work or skeleton, for all the other tissues and organs are gathered about or are attached to it or concealed and protected within its recesses. We must, therefore, conclude that creative energy began the work of construction with the skeleton, and that this structure must be the first to receive our attention.

But how is he to construct the skeleton without a perfect knowledge of the materials of which it is composed? This inquiry leads the student at once to an exhaustive study of the intimate nature of bone, for a knowledge of these facts must precede actual constructive work. Turning to the articulated skeleton as an object lesson to learn the principal functions of bones, he notices that: First, they must sustain great weight, and, second, they must act as levers in all of the movements of the body. As an architect, he knows that the structural peculiarities necessary to the performance of these functions are: (1) Hardness, to sustain weight; (2) lightness, to facilitate movement; (3) elasticity, to resist violence. Here are three nearly opposite qualities to be combined in one tissue, and his curiosity is intensely excited to discover the thoughts of the Divine Architect as He proceeds to solve the difficult problem. But we will not follow the student in his study of osteology, or the science of bone. We assume that every phase in its development from the selection of its constituent materials to their final organization must interest one who is seeking as an inventor to determine its adaptation to the purpose for which it is created. He can but marvel at the wisdom that takes certain salts of the earth and combines them with a peculiar kind of animal matter in such manner that these heterogeneous substances by some unknown and unknowable affinity create a new substance having the qualities of hardness, lightness, and elasticity; qualities essential to bone in the performance of its varied functions in the skeleton. Scarcely less wonderful to him is the development of bone from the osteal cell and the conversion of the body of the cell into a lakelet, through the medium of which the new bone is nourished by hydrostatic pressure. And as he follows the formation of bone to its completion, he discovers in the construction of its tissue the demonstration of two new and very important principles in physics. The first is that a hollow cylinder is stronger than a solid shaft of the same size. This principle applied in mechanics economizes the materials employed and renders the structure comparatively light, thus adding to facility of movement. The result is beautifully illustrated in the long bones or levers of the skeleton. The second principle is the Gothic arch, which gives the greatest power of sustaining weight with the least amount of material; the greatest elasticity with the highest degree of lightness.

Having completed a minute study of bone and obtained an accurate knowledge of its constituents, its methods of development, and the structural arrangements adapting it to its various purposes, the student is prepared to advance to the actual construction of bones, and of placing each in its proper position in the skeleton.

Surveying the skeleton as a whole, the question again arises, Where shall constructive work begin? In other words, Which series of bones was first created? His answer must be determined by recalling the principle of construction of all machinery, viz., the central or axial part must be made first. Applying this principle as he critically examines the articulated bones, his attention is at once arrested by the series which constitute the spinal column as not only central in location, but obviously the other bones are attached to it in such manner as to prove that they depend upon it in the performance of their functions. He is warranted, therefore, in concluding that the spinal column must have been the part of the skeleton which first received the attention of the Creator.

But this conclusion does not solve the question as to the initial point where construction began, for the spinal column is constituted of many bones. He has decided as to the series of bones first constructed, but he has not fixed upon the individual bone in the series. In selecting that bone he must again determine which is the most central and important as regards function. It must be noted that in this view a vertebra proper includes the corresponding ribs and their sternal attachments as described by Professor Owen in his great work on "Vertebrates." In that system, "each complete segment, called 'vertebra,' consists of a series of osseous pieces arranged according to a type or general plan, in which they form a hoop or arch above and another beneath a central piece; the upper hoop, encircling a segment of the nervous axis, is called the neural arch; the lower hoop encircling a part of the vascular system, is called the hæmal arch; their common center is termed the centrum." A vertebra, thus defined, he calls a "type segment," and the skeleton of his ideal, or "archetype" vertebrate, consists of a series of these perfectly formed segments as we see them in the skeleton of the serpent.

As the student critically examines the different vertebræ to determine with which the Creator began construction, he is impressed with the important fact that while the segments of the spinal column have a general resemblance to each other, as if constructed after one model, there are differences which become more and more marked when those of either extremity of the column are contrasted with those in the central or dorsal region. This region must be the point of departure in construction. On examining critically each vertebra to determine which is the "type segment" his selection falls upon the seventh dorsal, for all its parts are more complete than any other and its ribs are longer and more perfectly adapted to their functions. With the *seventh dorsal*, therefore, he concludes that construction must begin.

Taking this vertebra in hand to begin practical work, the student at once discovers that it is constituted of many individual parts, each adapted to its special function. Again, he must determine which part is the center or axis of the vertebra before he can positively decide where the construction work

originally began and hence where he is to commence his operations. Examining very carefully the several parts of a vertebra and comparing it with the others in the series, he notices that the body is the most important portion, for not only are the other parts arranged around and connected with it as a base of action, but it is the only constituent of a vertebra which is continuous throughout the entire spinal column. The body, therefore, or centrum, must have been first created. By this process of scientific inquiry and logical reasoning he reaches at last the initial point where the Creator actually began the work of constructing the human mechanism, viz., *the centrum of the seventh dorsal vertebra.*

Here, then, the student begins the actual study of what is, in a real sense, "practical anatomy." The seventh dorsal vertebra is the point of departure from which he is to develop, in serial order, not only the skeleton but the entire human organism. The science of anatomy, like kindred natural sciences, thus has its beginnings in a few simple principles or conditions, and out of them grow the complex forms which are so difficult to understand when studied independently and without a previous thorough knowledge of these fundamental facts.

As the student, now fully equipped for his task, begins constructive study, we may well regard him as Huxley's "skilled operator on a formless lump of clay;" "a skilled modeler shaping the plastic mass;" "the hidden artist with his plan before him, striving with skilful manipulation to perfect his work." The plan before him is the articulated skeleton, and the materials are the individual bones; the former for synthetical study or the placing of each bone in its proper position and the latter for analytical study or the minute examination of its technical peculiarities. His method is still that of an inventor and creator, for he will learn the nature of the function before he begins structural work. Having found the initial point of construction of the mechanism which he is about to create, and being thoroughly familiar with the rules governing his art, our artist-student, our "skilled modeler," "with his plan before him," enters upon his task with enthusiasm and pursues his studies with ever-increasing delight. We see him model with nicest skill the interior of the body of the seventh dorsal vertebra, filling it with gothic arches that it may sustain great weight and still be very light. No sculptor's chisel ever wrought in marble more artistic curves than those which he gives to the exterior covering. With "delicate fingers" he shapes the neural arch, "pinching up" the terminal portions of the laminæ to form the graceful spinous process. With mathematical exactness he cuts the articulating facets so as to secure a minimum of motion with a maximum of strength. For the hæmal arch he forms the ribs and curves them so that they shall perform the two-fold function of protecting the organs of the chest and aiding in respiration through their nicely adjusted articulations with the body and lateral processes. He finishes the hæmal arch with the costal cartilages and the sternum and, adjusting the several parts to each other, the seventh vertebra, the "type-segment," stands forth perfect in all its details, a beautiful specimen of high art. With its completion the student has acquired the key to a thorough knowledge of all the bones of the skeleton, for the remaining bones are but variations of the seventh dorsal, the "type-segment." And all of these variations from the seventh are simply designed to adapt other vertebra to new functions. Hence he proceeds with comparative ease in his constructive study of the spinal column below and above the seventh dorsal. As he descends he modifies each vertebra according to its function until he reaches the coccyx, where he preserves only a remnant of the body. As he ascends from the seventh dorsal more remarkable changes take place, as in the atlas and axis, but most strikingly in the bones of the skull and face. But in these irregular and curiously formed bones the "student-artist" recognizes only variations of the "type-segment," adapting parts or the whole of the vertebra to new functions. Even in the bones of the upper and lower extremities he discovers two vertebræ which have undergone extreme variations owing to the peculiar functions they have to perform.

Thus in our scheme of study the seventh dorsal represents the "Vertebrate Archetype" of Owen, which Holden says is "the grammar of all osteology." He adds, "Of this a student may rest assured, that however minutely he may have scrutinized the bones he cannot *understand* them unless he knows something of the vertebrate archetype; without this knowledge he is like one who speaks a language fluently, but is ignorant of its grammar." And we may add that he has acquired a chain of associated facts which will remain indelibly impressed upon his memory, and that will enable him to recall promptly the function and the structural peculiarities of every bone in all the emergencies of practice.

Having completed the skeleton or frame-work, our artist-student recognizes that it must be endowed with at least two forces to enable the coming man to perform the task of tilling the earth and subduing it. First, he must have the power of locomotion, or of moving from place to place, and, second, he must have the power of prehension, or of seizing and holding objects. In construction the student must have noticed that the bones were designed to move upon one another, and that those of the extremities take the form of levers. The question now before him is as to the kind of apparatus to be constructed to operate these levers, and how it is to be applied. Holding up before my class the seventh and sixth dorsal vertebræ in proper position, I asked, "How would you make these bones move on each other?" A first-course student replied, "Attach a rubber strap to their spinous processes." He stated a principle and a fact; the principle was that the apparatus with which one bone is to be moved upon another must have the quality of contraction, and the fact was that such a strap as he suggested, though not made of rubber, was already attached to their spinous processes. The incident illustrates the readiness of the student, whose mind is trained to devise structures adapted to perform functions, to anticipate the very existence and nature of the tissues which he is about to study. It serves also to accentuate the proposition that I then made to the effect that as these central dorsal bones were first constructed, according to our scheme of creation, we may logically conclude that to these bones were applied the first structures made to move the levers of the body. Here, then, at the seventh dorsal, we find the *type muscle*, and here we begin our constructive study of the muscular system.

Preparatory for constructive work the student must now acquire, first, an accurate knowledge of the histological peculiarities of muscles and of their classification, and, second, he must practically learn the nature and classification of levers—two most interesting subjects to the inventor, and which, thoroughly understood, give to the surgeon great practical skill.

Assuming that he has acquired this knowledge, he begins the study of muscles *in situ*. He must reject altogether the method pursued in the textbooks, which follows the order of dissections; for nothing could be more unscientific than to construct the

muscles beginning with the most superficial layer and finishing with the deepest muscles. Now the order of creation must necessarily have been the very reverse of this. If we apply the muscles with our own fingers, as I propose, we must place the deepest layer first and the superficial layer last. This method has this obvious advantage that the deepest muscles are usually simple and have a single action, while the superficial muscles are compound and complex in form and action.

It will be alleged that this method of study necessitates delaying dissections until the student has completed the review of the entire muscular system as given in the textbooks. It is true that he would have to learn the muscles of a part, as the trunk or a limb, from his book before he attempted its dissection. And there is this advantage in such an order of studying, that his dissection will be much more carefully and intelligently made if he has already a correct knowledge of the parts he is now practically demonstrating.

Recurring now to the adaptation of muscles to the levers of the skeleton to give the latter functional activity, the question again arises in the mind of the artist-student as to the point where he is to begin. In other words, "Which muscle in the order of creation was first applied?" Logically, the first bone created—the seventh dorsal, according to our scheme, —would receive the first attention. Now the articulations of this bone show that it has a limited motion on the adjoining vertebræ, and to effect that motion the greatest leverage would be secured by attaching a muscle to the spinous processes of the two bones, as suggested by the student. He was thinking the thoughts of the Creator, for we find in the interspinales muscles the identical elastic cords that he recognized as necessary for the performance of the first and simplest function of these bones. These simple structures, so small in the dorsal region, but so well developed in the cervical, may be taken as the first muscles applied.

Commencing then with the *interspinalis muscle of the seventh dorsal vertebra*, as the point of departure in the study of the muscular system, the student follows the line of constructive thought in the most natural and scientific manner to the final application of the last muscle to the terminal bones of the extremities. Throughout this entire study his dominant thought as an inventor is in each case, "What class of muscles must I select and where shall I attach them to the bones to enable them to perform the functions for which they were severally created?" Thus, as the skeleton developed from a single central thought, so the muscular system now grows under his plastic hand in symmetrical form from the little, delicate slip that he placed between the spinous processes of the seventh dorsal and its neighbor to the enormous, intricate, and complex erector spinæ, multifidus and complexus, muscles of the back which students, following the old method of study, usually group very properly under the term "*musculus perplexus*." Having completed the muscles of the trunk, he proceeds to apply them to the great levers of the extremities. In this part of his study all his inventive faculties are inspired with the keenest insight by the revelation of the marvelous forms of adaptation of muscular force to effect the infinite variety of motions of these levers. And the one fact that perhaps will impress him most is this, that all these muscles, even to the terminal phalanges, have as the basis of their action the spinal column, and chiefly the central dorsal vertebra where he began the study of both the skeleton and the muscular system. This arrangement and action of the muscles will appear as he traces the peculiar relations of one muscle to another, beginning with the spinal column and terminating with the extreme bones of either limb. Though in the series there may be several muscles, each having its special function when acting alone, yet it is evident that they may all act together as a compound muscle, and perform a new and quite independent action. This is strikingly illustrated by Professor Owen in the figure of a man stooping under a heavy load, which rests upon his shoulders The weight is sustained chiefly by the following muscles, viz., the erector spinæ of the back, the glutei at the hips, the quadriceps extensors of the thigh, the gastrocnemii of the legs, and the short flexors of the feet. Here are ten separate and independent muscles, extending from the spine to the ends of the toes, now united in their action to perform one function.

In the construction of the human organism we have now completed the frame-work and the apparatus which is to operate it. But as yet we have only an inert and inanimate object, quite incapable of performing the duties for which it was created. Our next inquiry as inventors must be, "How shall these muscles be endowed with force and these dry bones be stimulated to activity?" The result of creative thought and energy was the development of that marvelous and exquisitely beautiful mechanism the nervous system. Studying along the lines of creation, the dullest student becomes fascinated with the wonderful adaptation of means to an end which he discovers in every part of this system, but especially in the nerve-centers where the power is generated which moves the muscles to action. As in the study of the skeleton and muscular system the student learned the intimate nature of bone and muscle before beginning construction, so now the histological peculiarities of the materials constituting the nerve tissue are thoroughly learned and the special uses of each kind or form is fully understood. Then constructive work begins and the point of departure is again the seventh dorsal, because here is found the *type nerve-center* of which all others are only variations to meet special functions. This one nerve-center, thoroughly analyzed and understood, is the key to a ready appreciation of the peculiarities of every other, as was a knowledge of the seventh dorsal vertebra a key to a quick understanding of the special features of every other bone of the skeleton. Even in the complicated and complex forms of nerve centers of the brain the student readily recognizes the special variations of the "type nerve-center" made to meet new functions, and so appreciates the necessity of the changes that he forever retains them in his memory. Not less interesting when studied in order is the origin of nerves from the centers, the method of distribution through the medium of a plexus, their final termination in muscles and other tissues and their relations, in their courses, to other tissues.

We have now reviewed the construction of three great systems of tissues—the osseous for a frame-work of the mechanism, the muscular to operate it, and the nervous to give it energy. But it is apparent to us as inventors that this machine, being subject to "wear and tear," and hence to decay and death, must not only be supplied with the means of repairing waste, but of perpetuating itself when its life ends. These facts open new fields for constructive study, and the artist-student begins with renewed zeal to trace in his plan the origin and development of the digestive system: then its auxiliary, the circulatory system, and, finally, the reproductive system.

We need not follow the student farther. He continues his study and construction along the lines of original thought, always first recognizing a function

to be performed before he studies the apparatus designed to perform it. As he proceeds, all the details of the mechanism unfold in the logical order peculiar to the natural sciences, "pointing," says Holden, "to the One great cause of all organization."

A student who has in this manner thoroughly mastered the several systems of tissues theoretically finds their demonstration by dissection a constant source of delight. Every stroke of the scalpel is made with precision, and reveals a hidden thought of the Creator in new and living light, which engraves upon the memory of the dissector the details of function and structure so distinctly that, at all times and in all emergencies, this knowledge is immediately available. And I may add, as a final statement, that to the philosophical, devout, and creative mind, seeking knowledge along these lines of inquiry, the ecstatic remark of Galen is eminently true: "*The study of anatomy is a perpetual hymn to the gods.*"

640 Madison Avenue.

HEADACHE IN ITS RELATION TO DISORDERS OF THE GENERAL HEALTH.*

By WILLIAM M. LESZYNSKY, M.D.,
NEW YORK.

CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL, AND THE HARLEM HOSPITAL; NEUROLOGIST TO THE LEBANON HOSPITAL AND THE DEMILT DISPENSARY.

Headache is a frequent manifestation of the most varied disorders of the nervous system and of other organs. Being merely a symptom of so many different morbid states, it cannot be consistently characterized or described as a disease, although it is often of such a nature as to possess the significance of an independent affection. It may be so fleeting or transitory as to be more or less ignored by the patient, or it may attain such a degree of severity or persistency as to lead the sufferer to seek medical advice. Familiarity with its various forms is essential, for the practitioner is confronted by this symptom at almost every turn, and it is necessary always to bear in mind that headache is a frequent accompaniment of many constitutional diseases. Hence, a description and classification of headache, with suggestions as to the means of determining its causation, must prove of great practical value. According to many modern observers, we know almost nothing of the structures in which the pain of headache is felt, or the mechanism of its production. As the meninges, especially the dura and a large area of the cranium, receive their sensory supply from the terminal sensory branches of the trigeminus, and, as the meninges are also supplied by branches of the sympathetic nerve, it is reasonable to assume that headache is the result of direct or indirect irritation of these nerves. Psychical disturbances, in the form of depressing emotions, such as grief, worry, fright, etc., often produce headache. In such instances it must be due to processes originating in the higher cerebral centers through which superficial pain is perceived.

Headache must not be confounded with true neuralgia, in which the pain is paroxysmal in character and directly limited to the course of the nerve and its distribution. The idea that the location of the pain in any particular region of the head is always directly related to some special underlying, adjacent, or remote pathological process (excepting pericranial inflammation) has not been substantiated by clinical experience. No definite rules can be formulated in regard to this matter that will apply in every case. It may be said, however, after the perusal of the histories, and observation of a large number of cases, that such information, nevertheless, may prove valuable in suggesting certain lines of inquiry. The headache may be confined to the forehead, to the vertex, the parietal, temporal, or occipital region on one or both sides. It may be unilateral, as in migraine, or it may affect the entire head, and is then described as diffused or general, or it may occur in various combinations. It may be transitory, paroxysmal, periodical, or continuous, and may vary in location, degree, and character from time to time.

Headache, for all practical purposes, may be divided into two classes, functional and organic. The so-called functional forms of headache are, by far, the more frequent, and include those resulting from various constitutional or psychical disorders, and from causes not situated in the skull or cranial cavity, excepting the disturbance of special sense organs, such as the eye, ear, and nose. Some disorders of the cerebral circulation may also be placed in this category.

The organic form includes all types of intracranial disease, whether vascular, meningeal, or cerebral, and disease of the cranial bones.

My remarks are based upon a clinical study of nearly 5,000 cases observed during the last twenty years, and will be confined to a description of the functional forms of headache, and their relation to other morbid conditions, in which headache often obtrudes itself as a persistent or predominant symptom.

As the magnitude of the subject, as above outlined, will not permit of its adequate representation in the allotted time, migraine will be excluded from the discussion.

In a very large majority of instances in which headache is complained of it is due to toxæmia resulting from either constipation, or intestinal or gastric indigestion. The clinical fact has long been established that autointoxication of intestinal origin plays an important rôle in the production of headache, migraine, and vertigo, but such symptoms are evidently more or less dependent upon individual susceptibility. Constipation is not incompatible with apparent health, for some persons may be constipated for a week or more at a time without any complaint of digestive trouble or headache. For this reason the objection has often been made to the hypothesis of autointoxication of fecal origin. On the other hand, Bouchard, who has made a special study of this subject, believes that constipation should be regarded as a protection against intoxication. The lengthiest argument, however, will not controvert the familiar fact that thorough purgation causes the rapid disappearance of the headache and associated symptoms in most cases of this character. In these patients the headache is usually located in the frontal region, but is often diffused over the entire head. As a rule, it is not constant, and may or may not be associated with gaseous eructations. In some it is accompanied by morbid somnolence during the day and heavy sleep at night, while in others insomnia is complained of. Occasional attacks of vertigo may also occur. Intestinal indigestion, with or without constipation, is more frequently productive of headache through autotoxæmia than as a supposedly reflex cause. The urine is often of high specific gravity and may contain an excess of indoxyl.

It would seem that gastric indigestion, on the other hand (although in some instances occasioning toxic absorption), is more likely to produce headache by reflex irritation through the pneumogastric nerve from fermentation of food and gaseous distension of the stomach. Thus, headache, possibly due to both causes, is frequently an accompaniment of dilatation

*Read before the Harlem Medical Association, March 5, 1902.

of the stomach. The location of the headache is usually supraorbital or frontal.

Headache due to renal disease is of very common occurrence. Two forms are found in nephritic subjects—uræmic and congestive.

Either one or both may be present in the same patient. The uræmic form is due to the retention in the system of the constituents of the urine, and may manifest itself in any type of kidney disease, whether acute or chronic, and is often a premonitory symptom of a convulsive attack. The pain is ordinarily situated in the occipital region, extending to the neck. It may or may not be associated with somnolence, nausea or vomiting, etc., according to the degree of damage to the kidneys and arterial system. In some cases the headache may be accompanied by vomiting, vertigo, and optic neuritis, thus simulating the general cerebral symptoms of brain tumor. The congestive form arises in consequence of disturbed cerebral circulation in the presence of cirrhotic kidneys, with arteriosclerosis, cardiac hypertrophy, and increased arterial tension. Unless the urine is carefully analyzed, and the functionating power of the kidneys ascertained beyond question, the uræmic forms of headache will often pass unrecognized, and may lead to unexpected and serious consequences.

As so many physicians carelessly limit the urinary analysis to the reaction and test for albumin, it is well to bear in mind that in chronic interstitial nephritis albumin is often absent.

Two kinds of headache occur in rheumatic subjects. One is due to suboxidation and autotoxæmia, the headache being diffused and similar to that arising in other forms of toxæmia. The other is a true muscular rheumatism or myositis located in the scalp and affecting particularly the occipito-frontalis muscle and its aponeurosis. The pain is increased by active or passive movement of this muscle, and it is common to obtain a history of other attacks of muscular rheumatism affecting different parts of the body. These patients may also have suffered from acute or subacute articular rheumatism. The attack may last from a few hours to several weeks. Like other forms of myositis it is induced by exposure to cold. One of the worst cases under my observation occurred in a rheumatic subject after bathing the head in cold water and then sitting at an open window for a half hour or more.

Headache is frequent in gouty subjects. It may be due to toxic products of defective oxidation, or the result of vascular disease affecting the cerebral circulation. It is not unusually accompanied by interstitial changes in the kidneys. The headache and the irregular symptom-complex, often described as lithæmia, is an atypical form of gout, in which there is more commonly a sense of pressure and fullness about the head than actual pain.

Headache occurring in diabetics is often accompanied by hebetude and depression of spirits. As a premonitory symptom of diabetic coma, it is soon followed by delirium and dyspnœa.

In the early period of all acute infectious diseases headache is frequently a prominent symptom, and is usually described by the patient as generalized or frontal. As an initial symptom of typhoid fever, it is sometimes so severe and persistent as to demand special attention. The pain is often located in the occiput and back of the neck, and may be accompanied by photophobia, retraction of the head, and muscular twitching, thus resembling meningitis. Not long ago I saw the wife of a physician who had been confined to bed for several days with severe occipital and vertical headache. The pupils were contracted, and there was considerable photophobia and occasional mild delirium. She was supposedly suffering from meningitis, but was found to have typhoid fever, which took the usual course. On account of the severe general headache, the early period of acute croupous pneumonia may also simulate meningitis until the lung trouble has clearly developed.

In general, it may be said that headache frequently occurs in all conditions accompanied by fever. It is hardly necessary to mention, that, as a routine practice, the temperature should be noted in every case of acute headache, the character and frequency of the pulse, and the presence of fever being always suggestive of the probably infectious or inflammatory origin of the trouble.

Headache is often due to acute or chronic alcoholic poisoning, the nervous system being at times so sensitive that a small quantity of alcohol may produce violent but transitory general headache of a congestive type. Chronic alcoholic poisoning is often the cause of daily or constant headache, but it is commonly due to a combination of causes, such as toxæmia, interference with the digestive processes, and cerebral arteriosclerosis. It is often associated with cirrhotic changes in the liver and kidneys, and many of the attendant phenomena of these conditions.

In some individuals the injudicious and excessive use of coffee is productive of headache and a sense of fulness in the head.

Headache due to the toxic action of lead is a comparatively rare symptom. In some cases of chronic lead poisoning, however, headache does occur, and its cause should be recognized. It is probably due to the direct action of the lead on the cerebral nerve centers, or indirectly through the production of pathological changes in the liver and kidneys.

Headache is often an important symptom in neurasthenia, but it is not present in all cases. As a rule it is not general, but is commonly located in the frontal or occipital region, and is often accompanied by occasional vertigo and muscæ volitantes. The headache, which is usually slight in degree, is either continuous or occurs at brief intervals. In the majority of neurasthenics actual pain is not complained of but the sensations in the head are described as the feeling of "a constricting band about the forehead," "fulness in the head," as if there was "something pressing from within against the skull," etc. Frequently it is a sensation of weight or numbness, and occasionally throbbing. The headache and other sensations increase after fatigue, and are often diminished by rest. Difficulty in concentrating the attention is often present. As a result of these varied forms of cephalic paræsthesiæ, such patients are inclined, more or less, to indulge in excessive introspection. They often become morbid and apprehensive, dreading the possibility of a brain tumor or other serious cerebral disease. All of these symptoms are modified in proportion to the attention given them by the patient. The presence of other signs of neurasthenia, their development or increase through mental effort or emotional excitement, and the absence of evidence of organic cerebral disease make the diagnosis clear. Headache that is confined to a small spot (which for many years has been described as "clavus hystericus") is comparatively rare in this country, and occurs most frequently among the premonitory symptoms of convulsive hysteria. The scalp is sometimes so sensitive that the slightest touch is not tolerated without wincing. In the majority of cases of hysteria, however, the headache corresponds with that of neurasthenia. It may be limited to one side and thus simulate

migraine. In some instances it may be characterized as a veritable psychalgia.

While headache cannot be considered as a symptom of epilepsy, its occurrence is at times of great importance in the diagnosis of obscure cases. An attack of "grand mal" is often followed by severe general headache, which may last for several hours. This fact is of value in interpreting the cause of the headache when it is mentioned as occurring in the early morning on awaking. It is at times indicative of a nocturnal epileptic attack, and the diagnosis is positive when such headache is associated with soreness of the muscles and joints of the extremities, a bitten tongue or mucous membrane of the cheek, and wetting of the bed.

Ocular defects, such as errors of refraction and insufficiency of the ocular muscles, are a common source of headache. The two conditions may be found in various combinations. It has been claimed that fully 60 per cent. of functional headaches due to errors of refraction are caused by astigmatism alone, or in conjunction with other forms of ametropia. The headache is produced by strain on the ciliary muscles, and frequently arises in connection with hypermetropic astigmatism. The pain may be situated in any part of the head, but it is more frequently located in the supraorbital region. It may be persistent in character, and is often aggravated by using the eyes. It is relieved temporarily by the instillation of atropine, which paralyzes the ciliary muscles, or permanently, by wearing suitable glasses. Headache caused by insufficiency of the ocular muscles may affect any portion of the cranium, but is often located in the occipital region. It may immediately follow the use of the eyes, but usually this is not the case, the pain occurring at irregular intervals. At times it may develop into a typical attack of migraine, and is often associated with symptoms of neurasthenia. The claims of certain writers, that the lack of balance in the action of the muscles of both eyes is a prolific cause of headache, and various forms of nervous disease, have certainly been much exaggerated. The headache arises as a result of repeated or continuous unconscious efforts to obtain and preserve binocular single vision. It is a fact well-known to all ophthalmologists that so-called ocular headache does not occur in patients in whom there is a congenital or acquired absence of binocular vision, as such patients are known to habitually suppress the image in one eye. Hence, the causative element of "efforts at binocular fixation" is negligible under such circumstances. This occurs with high degrees of strabismus, paralysis of ocular muscles, when vision is greatly diminished or lost in one eye, and when there is considerable difference in the refraction of the two eyes. When headache occurs in such people, it is invariably due to some other cause. I know of a patient with ocular headache from muscular trouble, in whom the pain entirely disappeared after the accidental destruction of one eye. The improved methods in the examination of the power and action of the eye muscles introduced within recent years has led to a more accurate and thorough study of three conditions. Curiously enough, the muscular troubles, which occasion the greatest amount of discomfort to the patient, at times produce no evident changes in the gross appearance of the eyes. Hence, it is only after a most careful and painstaking investigation that they can be discovered and rectified. This is accomplished either by the use of suitable lenses to neutralize any existing refractive anomaly, and thus indirectly influence muscular action, or by surgical operation, or both. There must be a peculiar individual predisposition to headache, for there are persons who have both muscular and refractive anomalies without any symptoms of headache.

Various pathological processes in the nasopharynx may occasion headache, especially lesions of the inferior turbinated bones, adenoid growths, and polypoid obstruction to nasal breathing. Hence, headache is not an uncommon symptom in mouth-breathers. The pain is ordinarily located in the temporal region or forehead, and has often been known to disappear after the adoption of suitable surgical measures.

Headache occurring in patients with uterine or ovarian disease should not be looked upon as a symptom of reflex origin. It is merely one of many phenomena associated with a neurasthenic condition which so frequently accompanies intrapelvic disease in women. The headache frequently affects the vertex, but is more often general, and is at times accompanied by tenderness of the scalp. Other causes are usually operative independent of any local lesion of the uterus or adnexa. The morbid self-consciousness developed in many women who have, or think they have uterine or ovarian disease, is often sufficient in itself to engender a depressive form of neurasthenia with its usual form of headache and paræsthesiæ. The same may be said *mutatis mutandis* of affections of the male genitourinary organs.

Headache is sometimes the result of hyperæmia or congestion of the intracranial circulation. It may also be occasioned by cerebral anæmia. Active hyperæmia is due to paralysis of the vasoconstrictors permitting of distension of the arteries. The severe cases are attended by throbbing general headache, vertigo, tinnitus, muscæ volitantes, photopsia, insomnia, mental confusion, and delirium, all of which are made worse by lowering the head. The face and scalp are red, and the conjunctivæ injected. There are fulness and throbbing of the temporal arteries, and contracted pupils. In some persons such attacks occur periodically. The severe forms of this condition are fortunately rare. The milder degrees are not uncommon. It is usually due to mental overwork, emotional disturbances, alcoholism, and sudden suppression of menstruation in plethoric women. I have witnessed a similar, but slightly modified array of symptoms, occur periodically in young women, after removal of both ovaries. A prototype of this group of symptoms can be produced by the administration of various drugs, such as nitrite of amyl, nitroglycerin, etc.

Venous hyperæmia of the cerebral vessels is an important cause of habitual headache. It is most frequently chronic. The pain is of a dull character, and is often accompanied by a sensation of fulness and heaviness in the head. The face and ears may be slightly cyanotic in the more pronounced cases. Passive cerebral congestion is generally caused by mechanical hindrance to the return of blood from the head. Thus, it results from growths in the neck making pressure on the jugular veins, cardiac diseases, pulmonary emphysema, and persistent cough, as in pertussis. It may also be produced by a tight collar, or continuous flexion of the head. The headache and other symptoms are aggravated by straining at stool, coughing, sneezing, stooping, or muscular effort.

Anæmia of the brain, as a rule, is a part of a general condition of anæmia and malnutrition. It may be the result of arteriosclerosis including disease of the coronary arteries. Whether the general anæmia be of a chlorotic nature or from loss of blood, it is almost always accompanied by headache. The condition of cerebal anæmia in which headache occurs

is generally of the chronic form. The pain may be frontal, vertical, or diffused, and is commonly of a dull character. It is often associated with attacks of syncope, tinnitus, dizziness, incapacity for mental work, depression, and irritability. The pupils are usually dilated. The headache often diminishes or subsides when the patient assumes the recumbent position with the head low.

The diagnosis of the cause of headache depends entirely upon the patient's history, and the presence or absence of certain associated symptoms. This will be readily appreciated after a review of the conditions in which headache occurs, as either a predominant or a concomitant symptom. The general health of the patient must always be carefully investigated, particularly with regard to the function of the digestive tract and the action of the kidneys. While the seat of the pain is often suggestive, too much stress must not be placed on this indication, for in all forms of headache the pain may vary in its location from time to time. In supraorbital and occipital neuralgia the pain is more or less paroxysmal and superficial in character, usually being confined to the anatomical distribution of the nerve, and is, therefore, not a true cephalalgia. Continuous headache, lasting many days, with nocturnal exacerbations, should always lead to the suspicion of cerebral syphilis. It is always necessary to decide whether the headache is due to a functional disturbance, or the result of organic intracranial disease. A safe rule to follow in all cases of persistent headache, is to ascertain if any signs of cerebral disease are present. A constant general headache, which is accompanied by optic neuritis and frequent attacks of vomiting, invariably points to intracranial disease. Examination of the pupils should never be omitted. In hyperæmic forms of headache the pupils are usually contracted, while in anæmia they are found dilated. When the pupils fail to react to light, or are absolutely rigid, the vision being unaffected, it is highly suggestive of cerebral syphilis or some other form of cerebral degeneration. The ophthalmoscope often proves extremely valuable in diagnosis. Although abnormalities of the cerebral circulation may exist without evidence of such disturbance in the retina, the discovery of "choked disk," or optic neuritis, or varying degrees of hypermetropia, myopia, or astigmatism will often be the means of determining the cause of the headache. The most important use of the ophthalmoscope in cases of headache, is to determine the presence or absence of optic neuritis. While its absence does not exclude organic disease, its presence is presumptive evidence of some form of intracranial disease, such as basal meningitis, increased brain pressure from cerebral tumor, or the vascular degeneration associated with renal disease.

As previously mentioned, careful investigation of the entire organism is essential in every case, the most important element in the treatment of patients with headache being the recognition of the cause, as the pain is oftener dependent upon some underlying constitutional condition than upon organic intracranial disease. The discovery and correct interpretation of such facts should be the principal guide in the adoption of therapeutic measures. In the toxæmic form of headache, as well as in other forms, it is absolutely necessary that the large intestine be kept free from fecal accumulation, and that the action of the digestive organs be regulated by suitable diet, etc. All supposedly reflex causes should be rectified, but too much stress must not be laid upon the paramount importance of such disorders, for many patients seem to possess an inherited or inherent predisposition to develop headache upon the slightest provocation. It is generally desirable and universally advocated that in habitual headache any existing error of refraction or eye-muscle defect be corrected, and I am fully aware of the value in certain cases of such intervention. But, even when such conditions are discovered and remedied, relief from the headache does not always follow, for several causes may be operative in the same individual. Therefore, before saddling a patient with spectacles for slight refractive errors, or cutting the eye-muscles, or operating upon the nose for deviated septum, or replacing by operation a slightly displaced uterus, or suturing a trifling laceration of the cervix, etc., all other probable causes of the headache should be systematically eliminated.

Headache due to cerebral congestion may be relieved by the avoidance of all forms of cerebral stimulants and psychical excitement, regulation of the diet, free purgation by calomel and salines, and the administration of bromide of potassium, and fluid extract of ergot, every three or four hours. Severe cases require cupping or blistering over the nucha, and local blood-letting or venesection. It would appear, from the recent experiments of Leonard Hill and others upon dogs, that the application of ice-bags to the head as a form of treatment has practically no effect upon the cerebral circulation. Hence, the time-honored custom of using the ice-coil or ice-bag in cases of cerebral congestion or meningitis is without any scientific evidence as to its action. Its clinical value, however, is still an open question. When the ice-cap is used, it should always be applied to the shaven scalp. In headache from cerebral anæmia, rest in bed with the head low, and special attention to the cause (which is usually general anæmia) is of prime importance. The administration of cardiac tonics and the use of iron and easily assimilable food, generally prove successful when organic visceral disease is absent. When headache accompanies the infectious or malarial fevers, the reduction of the temperature by hydriatic or other appropriate measures, or the use of quinine, are usually efficacious. In every form of headache we are often forced to resort to the temporary use of local applications of dry or moist cold or heat, or some form of anodyne or counterirritant.

Antipyrin, acetanilide, phenacetine, caffeine with bromide of potassium, etc., or diffusible stimulants, such as aromatic spirits of ammonia, tincture of valerianate of ammonia, etc., and the various opiates or analgesics often prove serviceable as symptomatic remedies, but their selection should be left entirely to the judgment of the physician. The faith of the laity in so-called "headache powders" and the like has been more or less initiated and fostered by the medical profession, inasmuch as the trend of the medical mind has too often been misdirected toward the relief of the symptom—headache—without adequate investigation as to its cause.

Many of the statements that I have made may appear trite and commonplace, but this paper is only intended to serve in a suggestive way, by calling your attention to a familiar symptom, which is often treated in a rather haphazard manner, although it is really deserving of closer scrutiny and more careful attention in every case.

56 East Fifty-eighth Street.

An Orthopedic Hospital in Toronto.—A new hospital was opened about two months ago, in Toronto, for the treatment of deformities, especially in children. The hospital has accommodations at present for nearly fifty patients, about half of which number can be cared for in the free wards, the rest as pay patients in private rooms. There is also an out-patient department for such as do not need hospital care.

WHY THE OPEN-AIR TREATMENT OF CONSUMPTION SUCCEEDS.

By M. A. VEEDER, M.D.,
LYONS, N. Y.

THE one resource in consumption that appears really efficient is life in the open air. This was recognized, to some extent at least, even before bacteriology had become a science. But now that we have so much better knowledge as to the causation of consumption, there should be corresponding improvement in our understanding of the mode of its cure. Even when employed without precise knowledge, the efficiency of the open-air treatment is so clearly apparent that we may hope for greatly improved results from instituting careful inquiry as to just why it succeeds.

It may be thought that air in large quantities, and in rapid motion, dries and blows away the bacilli, but although this may have considerable effect on the expectorations it cannot benefit the tissues inside the body. Nor is it the purity of the air that destroys the infection. The bacillus of tuberculosis will continue to grow in proper culture media even when continuously exposed to air that is absolutely sterile. Nor is it the plentiful supply of oxygen that benefits the consumptive, the bacillus being of the facultative anærobic variety, which grows equally well in the presence or absence of oxygen. If there is any gaseous ingredient of the atmosphere that is specially likely to destroy the bacillus it is not the oxygen, but the carbonic-acid gas, which is most abundant, not out of doors, but in badly-ventilated rooms. Practically, however, the effect of this gas is unimportant in this regard, it being present in too small a quantity. In like manner traces of ozone, or of balsamic vapors, or of the saltiness of sea air, have little real effect, except to appeal to the popular imagination, as exploited in the prospectuses of health resorts; nor is it the sunshine encountered in the open air that destroys the bacillus in the interior of the body. The direct rays of the sun do undoubtedly destroy the bacilli in the expectorations, thus abating somewhat the consequences of the spitting nuisance. Nevertheless the inhabitants of the polar regions, where there is no sunlight for months together, are absolutely free from the disease, while in the tropics, where there is the strongest possible sunlight every day in the year, it is very fatal, so that sunlight cannot be an indispensable factor in determining the efficiency of the open-air treatment.

It is true that the air of badly-ventilated rooms is laden with ptomains derived from the breath, and that much of the depressing effect of in-door living is due to this cause. Avoidance of these ptomain poisons by good ventilation and out-door living is no doubt beneficial, but it is not adequate to explain why the open-air treatment of consumption absolutely destroys the bacillus of the disease. On the contrary, the ptomain originated in the breath of a consumptive would be most apt to be detrimental to the activity of the bacillus, on the principle of the antitoxin treatment, bacilli very commonly being destroyed by the products of their own activity. If this be the fact in consumption, it would be life in an atmosphere laden with these organic poisons, and not in the open air, that would do the most good.

In short, canvass the subject as we may, there is only one attribute of air that need concern us in the present connection, and that is its temperature. Either heat or cold may be carried to such a degree as to destroy, not only all forms of activity, but life itself. At the very outset of the studies which originated the science of bacteriology, Pasteur hit upon the idea of employing cold to prevent fermentation. Very early in his investigations he also discovered a curiously abrupt limitation of temperature effect in the case of bacillus of anthrax. This organism does not propagate at a temperature above 100°, so that birds, whose temperature normally is 105°, are not susceptible to its attacks, unless made to stand in cold water long enough to lower their temperature to the proper degree, whereupon it becomes fatal in their case, as it is in animals whose temperature normally is 100° or less.

This sharpness of limitation of temperature effects is especially well-defined in the case of the bacillus of tuberculosis, its ability to thrive and form colonies beginning almost precisely at the temperature of the human body, and extending, with some increase, a few degrees above that point. Hence feverishness of any sort, even when attended by a rise of temperature of but a degree or two, may light up tuberculous infection previously dormant, and an ordinary cold or other slight ailment may seem to become the starting point of consumption. Hence, also cattle and birds, whose temperature normally is somewhat above that of man, are very susceptible to tuberculous disease, and horses, whose temperature is below that of man, are immune. That there should be such limitation of effect as this is not more remarkable than that the temperature of the body should be practically a constant quantity, the slightest departure from which marks the beginning of ill health.

That a variation of two or three degrees of temperature should make such an enormous difference in the ability of bacilli to grow and produce their toxins is a fact of the utmost importance in connection with the control of fever processes in general. The direct application of cold to the body, as it has been used successfully in typhoid fever, pneumonia, and rheumatism with high temperature, is attended by instant effects, that appear to indicate that the bacilli, if not killed outright, are at least made unable to originate their toxins as freely as before. There is also relief from abnormal strain secured to the heat-controlling nerve centers of the body. But it is the activity of bacteria engaged in the origination of toxins that keeps up the temperature disturbance, and this activity being checked by the application of cold, heat regulation in the body at once takes care of itself. Even in sunstroke, in which high temperature is supposed to kill by the direct effect of heat on the nerve centers, it is very likely that death really occurs from toxins, originated abundantly by bacteria that would be harmless at a lower temperature, but which at a high temperature are able to overwhelm the body by the products of their activity. In other words, the symptoms in sunstroke are those of exceedingly virulent bacterial poisoning, for which, very curiously, there is no remedy better than the application of cold. This explains why everyone exposed to extreme heat does not die. It is only those who are subjects of particular species of bacterial infection that succumb, and what ordinarily would result in a slight illness becomes fatal. So, too, there are cases in which heat hinders the activity of bacilli of particular kinds, as, for example, when we use a poultice to control certain species of inflammation.

In like manner, the natural resources of the body concerned in heat control are brought more actively into operation by the administration of certain drugs; perspiration produced in this way, for example, having the same effect as the outward application of cold. Thus it becomes pre-eminently desirable that the whole subject of the use of drugs and other measures for reducing fever should be re-studied from this

*Read at the New York State Conference of Charities and Correction at Albany.

point of view. The determination of the critical temperature points in the growth of the bacilli in various diseases, and comparison of such critical temperatures with those that appear in the body in the course of the diseases in question, may give much better insight into the mode of operation of methods of treatment, with corresponding improvement in their use. In this as in all other cases, true science consists in determining accurately the nature of the forces in operation and studying their limitations.

In any event it is evident that large temperature variation controls growth and every other activity of all forms of life absolutely, the only additional point here insisted on being that in the case of the disease-producing bacilli there are critical temperature points at which small variations have very decided effect on particular forms of bacterial activity.

In the case of tuberculosis habitual out-door living, including sleeping in a cool room at night, has the effect of large temperature variation so far as the lungs are concerned, and of small temperature variation so far as the rest of the body is concerned. So we have two classes of cases, in one of which the bacillus may be subjected to very great lowering of temperature in the lungs, and in the other to relatively very much smaller temperature changes elsewhere in the body. It is corroberative of the position taken in this discussion that the greatest benefit from the open-air treatment occurs when the disease is located in the lungs, and the least when it is confined to the bones or other deep-seated tissues, it being more directly accessible to the effect of cold in the former case.

That it is possible to lower the temperature of the lungs to a considerable degree by the inhalation of air such as is met with in ordinary out-door living, may be shown positively by comparing the temperature of the air exhaled with that inhaled. The air that has passed through the lungs at the ordinary temperature of a living room reaches very nearly the temperature of the body, but out doors the air exhaled may fall short of this as much as twenty or thirty degrees, constituting a decidedly large temperature variation from the point at which the bacillus of tuberculosis thrives, and is able to produce its toxins. If the bacillus is anywhere in contact with air so cold as this its growth and other forms of activity must be greatly retarded, and there is very good evidence that this is the fact in the lungs. It is probable that the bacillus is located very superficially in the mucous lining of the air passages for weeks or months after infection, acting like inert foreign matter, such as dust particles, in this location, until growth begins, and the tissues are invaded superficially at the outset, but more deeply later. If at this stage the individual infected houses himself up in a warm room constantly, the infection gains a firmer foothold and the chances of recovery diminish. But, on the other hand, if there is out-door living, even of the most primitive character, there is not only improvement, but entire recovery in a considerable proportion of cases. The colored people of the South in their cabins and shanties before the war were free from the disease, as they are not at present when living under much better surroundings in the cities. It is Arctic cold, and not cod liver oil, that gives the Esquimau his immunity. Life on a farm, or in a lumber camp, or at a health resort in the woods, or on a sea voyage, or riding about the country, all requiring much time to be spent out doors, have been found curative. Even in the tropics the nights may be sufficiently cool, and there may be days and parts of days cool enough to prove effectual on the principle that has been stated, but it is evident that very much more care and skill will be required than in colder climates.

Furthermore, habitual inhalation of fresh, cool air has a tonic and bracing effect, rallying the very forces of the body most concerned in ridding it of tuberculous infection, improving nutrition, bringing restful sleep, and through the pleasurable exercise incident to out-door living, quickening and deepening the respirations, and thus promoting the local effects of cold where it is most needed in the lungs. Such tonic effect is increased by the sunshine and diversion of mind incident to such mode of living. It is not a question of cold storage or of life in a cave at a constant temperature with a view to the absolute freezing out of the germs of such disease. In a culture tube the bacillus is simply made dormant by a degree of cold that proves fatal to it in the lungs. It is the resisting power of the body that destroys the germ, benumbed and weakened by a lowered temperture. Hence it is of great interest and importance that the very cold which hinders the growth of the bacillus helps the body to react against it. In short, out-door living and inhalation of cold air must be so managed and carried to such an extent as to stimulate the patient as well as discourage the bacillus.

There should be no discomfort through inadequate clothing, it being the local application of cold to the lungs, and not to the external surface of the body, that is effective. Indeed, warm clothing is of service by enabling colder air to be taken into the lungs without depressing effect. It is better also to become habituated to this sort of living somewhat gradually, the body, when enfeebled by disease, requiring time to react, and exposure to cold without reaction being injurious instead of beneficial. The patient must appear rested and not exhausted by the measures employed.

If reaction does occur, the ability to digest food improves also, and it becomes possible to aid recovery by forced feeding, which likewise enables greater cold to be borne without depression. It is not fat accumulation through forced feeding and rest in bed that is required, however beneficial such a regimen may be in nervous prostration. It may be well to begin in this way with a patient who is greatly exhausted, but as soon as possible the rule should be forced feeding and life in the open air.

The effect of improved nutrition of this sort is enormous. It has been found possible by forced feeding to determine the sex in bees and tadpoles, showing what a profound influence nutrition has upon vital processes. If it is possible to modify the development of sex by such means it surely is possible to modify in like manner the resisting power of the body against disease. Thus it becomes evident why the bacillus of tuberculosis is destroyed by a degree of cold applied to the lungs that would have no such effect outside the body. The germ made inactive by the lowering of the temperature is consumed by processes akin to digestion.

The question is often raised as to the possibility of destroying the microbes of disease without injury to the patient, but we have here a case in which the very thing that tends to overcome the microbe benefits the patient through stimulation of the vital forces in the manner that has been indicated. It is a two-edged method, cutting both ways.

The writer has entertained these views in regard to the curability of consumption for nearly twenty years, and has witnessed a considerable number of instances of recovery in conformity with them, mostly through change of occupation. One patient left a store and went on a farm, another went to sea for several years, another became a house-to-house canvasser, another rode about the country buying

produce, another, who had been to Florida without improvement, engaged in engineering work on a railroad in the winter in Canada, another made no change of occupation, but was simply much in the open air and slept in a very cool room at night. All these were unmistakable cases of tuberculosis that recovered, and have remained well for years. The failures observed during the same period, aside from those due to lack of conformity to the proper regimen, were due, for the most part, to alcoholism, depression due to financial and other anxieties, violent coughing and irritation of the throat from laryngeal extension of the disease, and especially to pus infection in addition to the tuberculous, a thing to be avoided, if possible, at all hazards, as it lessens the patient's chances greatly. There are cases also which, with our present knowledge, are best suited to surgical intervention, the disease being located in the bones, or the peritoneal cavity, or elsewhere, inaccessible to the local effects of temperature change.

But there are many cases in which such change of occupation as would be advantageous is not possible, or in which the patient does not use proper judgment, and needs instruction and care. For these cases, and generally, there is a rational basis for the organization of sanatorium treatment, not for purpose of quarantine, which is impracticable, because of the great number of cases, but for that of starting those who are in the initiatory and curable stages of the disease on the road to recovery, teaching them the regimen needful for their own salvation, and likewise the measures necessary for the protection of others, so that, after a period of sanatorium discipline and instruction along the lines indicated, they may go to their homes without detriment to themselves or others. The adoption of such a policy would tend also to lessen materially the prevalence of the disease through the diffusion of correct ideas among the general public. Sanatoria conducted on these lines would not become mere homes for consumptives, over whose doors might justly be placed the inscription, "Who enters here leaves hope behind."

With the enlarged resources of State aid every detail of the subject might be worked out successfully, and we should know just what to do with pus cases, and pulmonary cases, and those of a laryngeal nature, or those in which the bones and other parts of the body are affected. The records of such institutions also might be made to contribute valuable information as to the vulnerability of special organs and tissues of the body, due to defective development, heredity, and the like.

From the general course of the discussion it may be inferred that mountain climate quickening and deepening respiration, and increasing the local and tonic effects of cold, is advantageous, but not indispensable, except perhaps in warm countries. In temperate regions sanatoria may be located successfully almost anywhere, and in many cases the proper principles of treatment may be carried out successfully even in ordinary medical practice. In perfecting the regimen necessary, and in studying the selection of cases, and other phases of the entire subject, the enlarged resources of State aid would yield results not to be had in any other way, and repaying any expenditure involved a thousandfold.

Women Medical Students at Berne.—In the University of Berne, Switzerland, there are 252 women enrolled in the medical department and but 199 men. Almost all the women students are Russians.

COLD AND DISEASE.

By H. RANDOLPH TUTHILL, M.D.,
BROOKLYN, N. Y.

In the etiology of disease, cold has long been recognized as an important factor. It is not merely the existence of cold, *per se*, that we credit most often with causing or inciting the production of disease, but rather the sudden appearance of cold, as implied in an abrupt lowering of the temperature of the air about us, to which the body has not had sufficient time to accustom itself. Sudden changes in atmospheric conditions, and exposure to dampness and currents of air, as a result of which the surfaces of our bodies become cold, wet, or moist, may exert a peculiar influence upon our physical mechanism which tends to disturb its normal action, and, therefore, produce disease.

There are many diseases which we attribute largely to the influence of cold, such as coryza, bronchitis, and the various neuralgias, as well as acute congestions of the kidneys and other organs. But there are diseases which we know to be caused by specific microorganisms, with whose production or inception cold likewise appears to be intimately associated. In the early history of pneumonia, exposure to cold occupies a well-established place, as a causative agent, in the popular as well as in the scientific mind.

Again, there are other diseases of a contagious and infectious character, such as diphtheria, and also the exanthemata, which often begin in an insidious manner, and cases of such diseases are occasionally seen which present no history of direct exposure to contagion, but rather a history of exposure to dampness or cold. We often notice that the exanthematous diseases are accompanied by congestion and catarrh of the bronchial, pharyngeal, nasal, or laryngeal mucous membrane, and, indeed, such signs may manifest themselves at the very onset, before any other symptoms have made themselves apparent. We must admit that the influence of cold can have but a contributing effect in the production of diseases which we are positively, or comparatively, certain are the results of infection by bacteria. But the question might be asked, How can cold contribute to the production of such diseases?

The bacteriologists tell us that pathogenic bacteria are often found in the buccal cavities of healthy persons, and that they may be present for a considerable length of time upon the surface of mucous membranes without manifesting themselves by producing disturbance. The pneumococcus has been found for months at a time in normal saliva, and the Löffler bacillus has been found in normal throats. And that these microorganisms are able to remain within the buccal cavity without causing any harmful effects, we know to be due to that peculiar power and state of the tissues which enables them to resist and counteract infectious and noxious influences, and which we call vital resistance. The vital resistance of individuals depends upon their general well-being, environment, manner, and condition of life. The vital resistance of individuals is subject to constant change, and when we consider the fact that we carry pathogenic bacteria about in our mouths, and on the surfaces of our bodies, and that the air which surrounds us during our existence may contain multitudes of them, we can readily understand how narrow a margin often actually exists between health and disease. It may take but a very slight cause to derange the equipoise of the system, and lower

vital resistance—at which times nature might be said to be momentarily off her guard—and hence furnish an advantage to our minute, invisible foes. The influence of cold appears in some manner capable of lowering the vital resistance of individuals.

We are all familiar with the phenomena which are designated by the words "taking cold." We notice that these phenomena consist, at first, in the congestion of mucous membranes — noticeably throughout the respiratory tract—which is accompanied by a cessation of secretion from the mucous glands. The equilibrium of the circulation is disturbed, resulting in stasis of the blood current, the engorgement of capillaries, and, therefore, local congestions. As a consequence of this engorgement of capillaries, and arrest of secretion from the glands, the mucous membranes become red, and feel dry and harsh. Leucocytes, red blood-corpuscles, and serum escape from the vessels into the tissues, and the parts become œdematous. Desquamation of epithelium takes place on the surface of the mucous membranes, increased proliferation of the deeper epithelial cells occurs, and finally a reaction sets in, and the mucous glands pour out their secretion in great quantities.

"Taking cold" implies exposure to dampness or cold, which appears to produce a shock to the nerve centers, reflexly, by acting primarily upon the peripheral nerve endings. As a consequence of this shock a sensation of chilliness is felt, and the functions of certain tissues and organs are temporarily arrested or embarrassed.

The air we breathe is sifted, so to speak, by the Schneiderian membrane, and the mucous lining of the mouth, pharynx, larynx, and the bronchi, bacteria being arrested by the ciliated epithelium upon those surfaces, and kept adherent to them by the moist, tenacious mucous secretion.

Experiments have shown that normal saliva has the power of destroying the vitality of a certain number of pathogenic bacteria. According to Sanarelli, as mentioned by Sternberg, the diphtheria bacillus was not destroyed in filtered saliva, but ceased to develop and multiply in it, showing that the saliva had at least an inhibitory action. In these experiments 10 c.c. of saliva that had been sterilized by filtration through porcelain were found to be capable of preventing the growth and development of small numbers of pneumococci, although when larger numbers were added to this given quantity of saliva, some survived and developed. Human saliva consists of the secretion of the salivary glands, together with the secretion from the mucous glands of the mouth. It is very probable that the mucous secretion poured out by mucous glands upon mucous membranes also exercises a destructive, or, at least, an inhibitory action upon pathogenic germs. In nearly all diseases or inflammatory conditions of mucous membranes, we notice that after a time a great outpouring of mucus takes place, which would incline one to the belief that it is a protective measure on the part of nature; for the more we observe nature's ways, the more we are forced to the conclusion that her methods are always for the best, and that there is a well-founded reason for each of her acts.

If we interpret her moves aright, we will find that she will make, and is continually making, strenuous efforts in our behalf, and, therefore, that whatever she does is done with the intent to accomplish a beneficial result. As to whether bronchitis, coryza, and kindred affections are caused by the action of bacteria we are not certain at the present moment. But we do know that they are generally occasioned by exposure to cold, and that in their course, as well as in the course of an inflammatory condition of the intestinal mucous membrane, namely, diarrhœa, also largely ascribed to the influence of cold, we find this great activity on the part of the mucous glands, which has just been referred to, as a defensive act of nature.

Let us assume that the secretion of the mucous glands exercises a destructive, or, at least, an inhibitory action upon pathogenic bacteria; that these bacteria, carried about in the air, upon being arrested by the ciliated epithelium on the surface of the mucous membrane lining the entrances of the body, are kept adherent to this membrane by the moist, tenacious, mucous secretion, which, while it holds them, also acts upon them, devitalizes them, or thwarts, or hinders their development, and prevents them from being carried farther, and so gaining access to the interior cavities of the body. In other words, let us believe that nature mounts guard at the portals of our system, and posts her sentries to challenge the right of way to all intruders. We are told that expired air is free from bacteria, which inclines one to the belief that many that gain entrance to the respiratory tract are destroyed.

What is to hinder the supposition that during the arrest of secretion from the mucous glands, following exposure to cold, the pathogenic bacteria present at the time upon the mucous membrane of the mouth, nose, or pharynx being for the moment no longer restrained in their activities, may begin to develop, and either attack the epithelium in their immediate vicinity and find a nidus beneath its surface, as happens in diphtheria, or, being set free, and no longer adherent to the epithelium, owing to the absence of secretion and the dry state of the membrane, may be carried farther by currents of air, and reach the alveoli of the lungs, in the case of pneumonia. The local congestion and increased temperature of the parts would tend to stimulate such bacteria to great development and activity. Thus the microorganisms, having found a favorable breeding place, could multiply rapidly, throwing off the toxins which, upon being absorbed, produce poisoning—and all this during the temporary lull in nature's watchfulness. Then, when reaction sets in, and the glands pour out their secretion with renewed energy, the intruders might have gained such headway as to be able to repel and defeat the attempts to destroy them. The dry, congested condition of mucous membranes, accompanied by an arrest of secretion from the mucous glands, which follows exposure to cold, may last for hours or days before reaction takes place.

Many contagious and infectious diseases, especially the exanthemata, usually present pathological changes in the pharynx, at the very onset, often before any pathognomonic symptoms have manifested themselves, and there is some reason to believe that the toxic substances producing these diseases may find their way into the pharynx, attack the mucous lining of the pharyngeal wall,and become absorbed by the lymphatics.

When the tissues of the body are in a normal condition, individuals may be able to react promptly after exposure to cold, and prevent the inception of disease; while those whose systems are debilitated may not be capable of rallying the forces of nature to the attack with sufficient promptness or energy to repel the onslaught of bacteria.

However, any exposure to cold, to draughts, and to dampness, is dangerous, and should be avoided as much as possible, in order to prevent chilling of the

surface of the body and its attendant ills. But when such chilling does occur, in addition to a prompt and suitable stimulant to ensure quick reaction, and a brisk cathartic to aid in the elimination of toxic material, it would seem advisable to spray or gargle the mouth and throat well with some antiseptic solution.

83 Monroe Street.

THE CLOSE ANALOGY OF TRACHOMA TO ADENOIDS.*

By RALPH OPDYKE, M.D.,
NEW YORK.

ASSISTANT SURGEON TO MANHATTAN EYE AND EAR HOSPITAL; INSTRUCTOR ON DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

I have the honor to address you this evening on the relationship of trachoma to adenoids. In order to arrive at the necessary conclusion of my recent investigation, I must needs consider matter familiar to you all, and I ask your patience meanwhile.

The subject was forcefully brought to my notice as a result of examinations made on the children of this city during the present year, and at the request of our Commissioner of Health, Dr. Lederle. These children were examined with regard especially to catarrhal and contagious diseases of their eyes. The results, as since published, you are all familiar with. Were I to change the figures, of the trachoma cases in particular, it would be to increase rather than to decrease them. Especially would I feel prone so to do as a result of daily examinations of hundreds of children at the public baths of the lower East Side. Here I found the percentage of trachoma as high as 16 to 20.

In these examinations of many thousand children, I so frequently found adenoid vegetations of the superior and posterior nasopharyngeal space in those affected with severe forms of trachoma that I was forced to take it into serious consideration; especially was this the case in the co-called "operative" forms. Here, on an average, two out of every three cases had pronounced adenoid vegetations, with all the typically marked symptoms of this affection.

The same condition of affairs I found present, not only in the lower East Side schools, as anticipated; but, to my surprise, also in the uptown West Side schools, notwithstanding their better facilities and healthier children. Here the average was even more, and one out of every two trachoma cases had adenoid vegetations of the pharynx. More recently, I have carefully watched the trachoma cases assigned to me for treatment at the several hospitals with which I am connected, and here, too, I have noted practically the same adenoid involvement as previously stated. To emphasize this state of affairs, and to give what seems to me a reasonable and practical explanation for it, and especially to lay stress on the seriousness of the existing conditions, is the object of this paper.

To prove, first, that the abnormally large adenoid vegetation in the pharynx is in existence antecedent to the trachoma complication of the lid, we need but recall to mind that this same adenoid vegetation is present in the throat before birth. Also, that recognized authorities tell us that adenoid or lymphoid structure in the lid is not sufficiently developed for the inception of the insidious trachoma till the child is several years of age. And to have a true trachoma, it is recognized that there must needs be this came adeno-lymphoid structure in the lid.

Secondly, both diseases have many of the same etiological factors—poor environment, bad hygiene, overcrowding, climatological changes, heredity, and the dyscrasia; in fact, any condition producing a local irritation or a general disturbance is prone to set up a rapid over-development of the adenoid obstructive nasopharyngeal growth. Or, as Kyle tersely puts it, "Given any dyscrasia producing a tendency to general glandular involvement, and let the same be increased by lessened physiological resistance and diminished vascular tone, and we will then expect lax structures, especially mucous membranes, so easily engorged and liable to watery infiltration, because of their frequent lymph channels, to be the first seriously to suffer." The cause of adenoids is, therefore, clearly recognized. This, unfortunately, cannot be said of trachoma. So many different factors here present themselves for consideration—quite a paper on this subject alone might be written.

Even the generally-accepted theory of its virulent contagiousness is combated by such recognized authorities as Gunning, Vennemann, and Norris and Oliver. We are not now in the midst of a trachoma epidemic—it is rather that the many thousand cases are being ferreted out and brought into public notice. Until a specific trachoma germ is finally settled upon, the etiology of trachoma will remain a mooted one.

Meanwhile, we must fall back on, as relative factors, the races most susceptible, viz., those of Eastern Europe and Western Asia, and the American Indian, excluding the negro, as a rule. Percentages in the nations affected range from 10 to 60 per cent.

Upon one fact all the authorities seem agreed, and this very fact follows out my line of thought. It is, that the liability of attack depends most strongly on the state of the general health at the time of exposure. That there must needs be the required lowered vitality of the general health, due to errors of life, as diet, hygiene, environment, etc. I claim that none of the above conditions can possibly bring about this condition more forcefully than the appalling evil results subsequent to adenoid vegetations in the pharynx. If, as we know, over 80 per cent. of our acute and chronic ear cases result from this condition alone, why, then, may not equally serious lid complications ensue? It is not, therefore, always necessary to hunt for certain race or hygienic causes, or even contagion; these may be but addenda to a more exciting and persistent factor.

Other arguments will bear me out, for, we may have a child with marked trachoma in one eye, and the other eye not affected. I have frequently seen a single trachoma case amongst a number of children in adjacent seats, in a class room, and these with perfectly healthy lids. But let a child with adenoids be seated near the trachoma case, and it is a matter of only a short period of time before the one exposed is likewise affected. The contagious factor may have been present, but it needed only the lowered vitality, resulting from the adenoids, to make the exposure effective. I can find no authorities emphasizing or even mentioning this line of thought, nor do they give trachoma as one of the sequelæ of adenoids.

Thirdly, consideration of the pathology of adenoids and trachoma is very important. That of adenoids may be briefly stated as follows: (1) The so-called soft variety—composed entirely of friable, over-developed lymphoid structure. (2) Œdematous or cyanotic form, with no increase of glandular structure, the enlargement due solely to venous stasis. (3) Hard or hyperplastic variety—here an increase of lymphoid tissue with a decided overgrowth of the connective tissue elements is present. (4) Still more dense form—in which the inflamed

*Read before the Section on Ophthalmology, New York Academy of Medicine, November 17, 1902.

lesions of the lymphoid structure unite with inflammatory organization of the connective tissue elements and there follows more or less contraction and, later, atrophy. In the adenoid vegetations, when removed, we can easily discern these different varieties, and they are generally differences of degree, after all, for one stage passes into the following, if their removal is sufficiently long delayed. In other words, then, the abnormally-developed adenoid vegetations are simply an increase of the normal adenolymphoid material, with more or less connective tissue stroma infiltration, the one or the other being in excess, according to the nature and severity of the cause.

The pathology of trachoma, on the other hand, is much more complex, and authorities have agreed to disagree. Some hold it to be an entirely new growth of a special pathological nature; others, that it is simply an enlargement of the lymph follicles, and that the subsequent changes are related and traced to the same. Wright holds that there appears no true granulation material; for the mucous membrane in trachoma is never ulcerated. Juler claims that the so-called granulations are elevations composed of aggregations of lymphoid cells beneath mucous membranes and with a partial fatty degeneration of these cells nearest the surface. Leber has found in the trachoma follicles large white cells, which he called corpuscle cells, yet these same cells were identical with and to the corpuscles of the lymph follicle of a normal conjunctiva. Again, there is nothing histologically distinctive in a trachoma granule; it is simply a mass of gelatinous material composed of small round cells, delicate connective tissue fibers, and of newly-formed blood vessels, and enclosed in a highly vascular capsule. (Norris and Oliver.) All authorities agree that the adeno-lymphoid tissue is always seriously involved in trachoma, and that in the repeated attacks none escapes. Stephenson concludes that follicular conjunctivitis never becomes a trachoma, for, as he says, the former is a true manifestation of an adenoid activity, and to that extent, physiological, and it, therefore, never produces a destruction of tissue.

If trachoma is a new growth, is it a cause or a result of inflammation? Perhaps the general inflammation is not the first step in the process; but, on the contrary, sets in later and forms, as it were, a "vicious circle." Excellent authorities tell us that the inoculation of trachomatous material does not produce a new trachoma; yet its secretion, if injected, may; but if a new inflammation be produced it does not become a true trachoma unless the constitutional vitality is of a sufficiently low grade to warrant it. Even in 1876 Norris and Oliver stated that trachoma was a local manifestation of a dyscrasia. Like tuberculosis, it is a deposit or development of foreign material in tissue, thus leading to its destruction and, later, to a formation of contracting cicatrices. Also that, for its proper development, a certain predisposition or constitutional susceptibility to the peculiar exciting cause was necessary. To this opinion many are now leaning, and rightly so, too, I think. Burnett believed there was a form of dyscrasia having a predisposition to this disease, trachoma. Such authorities as Nettleship, Reich, Stilling, and Kucharsky hold that trachoma is a true sequelæ to follicular conjunctivitis; whereas, Sæmisch, Swanzy, Meyer, and de Schweinitz claim it to be a separate and distinctive disease.

It may not be amiss to quote an oculist who is a recognized authority on its pathology. "These little trachoma bodies or lymphoid follicles, deeply seated and crowding in, compress the true conjunctival tissue, and its circulation lasts only a varied time. Soon existing vascularity is increased, the follicles grow larger, softer, and their contents are forced out by pressure, and later unite with the hypertrophied conjunctival papillæ. During this period there is the great reaction and secretion of purulent material, and here the risk of contagion and corneal involvement is greatest. Fresh follicular eruptions now take place, during the above-described fatty degeneration and softening, and the same process repeats itself. The "granulations" are with difficulty distinguished from the papillæ and, later, are united with them. Finally the cicatrization of the old granulations unite with new so-called ulcerations, and we have scar tissue, or a true cicatricial trachoma."

It is needless for me to mention the very many forms of this disease, each name designates the kind of tissue in excess. I merely mention the so-called non-follicular trachoma, in which, as Knapp says, there is inflammatory material truly analagous to nasopharyngeal adenoid vegetations. Here, then, we have, in a word, hypertrophy of the normal lymphadenoid tissue, a sympathetic enlargement of the papillæ, and a serous infiltration, and later a fatty degeneration succeeded by, finally, a cicatricial formation. These processes, are, again, but one of degree, and are in close similitude to those earlier described as present in the pathology of adenoid vegetations.

Thus, then, to sum up, we have two distinct diseases in different parts of the body and adjacent to different organs, and with their etiological and pathological factors very closely analogous. We have proven the adenoid vegetation to be the primary factor, and we should, I think, give the benefit of the doubt to the trachoma as being its true sequel.

If such, then, be the case, and you, one and all, find adequate reason to agree with this supposition, it goes without saying, that active measures should be undertaken to stamp out, or, at least, to lessen the prevalence of trachoma by preventing its inception.

Trachoma exists, as I found in my examinations, amongst all classes. Refractive errors do not seem to increase its frequency or its intensity; in fact, children with trachoma, I have found, by frequent examinations, to have surprisingly good sight, often even $^{20}/_{30}$. Eye strain or poorly lighted classrooms are not important factors. Poor environment, hygiene, etc., are important only so far as they tend to lower the vitality. Here is the keynote: Given lack of general tone and a lymphoid dyscrasia, and, like a fire suddenly flaring up from a dying ember, a seemingly healthy lid becomes a horrible mass of cicatricial ridges, with all the serious consequences to the adjacent organ imminent.

I cannot, therefore, too strongly urge serious consideration of this threatening evil. If there may be sufficient uniformity of opinion on this subject, it is certainly our duty to urge our brother practitioners to insist, as far as is possible, in instructing both teachers and parents how to recognize the typical adenoid symptoms. The adenoids thus diagnosed are to be at once removed, and by this means not only will cases of trachoma be far more apt not to recur, after once operated on; but, more important still, the prevention of new cases will be successfully combated. In this way can the frequent number of cases of on-coming deafness and blindness be gradually and effectively checked by this simple preventive procedure.

137 West Sixty-ninth Street.

Women Physicians in Paris.—Out of a total of 3,641 practising physicians in Paris only fifty-seven are women.

Brain Tumors.—Max Mailhouse reports three cases: 1. *Endothelioma of base:* A Hungarian woman, aged forty years, admitted March 13, with a history of headache for at least a year, died April 27. She showed disorientation, incoherence, muttering, nocturnal restlessness, and screaming; exaggerated knee and plantar reflexes, double clonus; dilated pupils, double optic neuritis; perverted smell (odors disagreeable); headache; slight weakness of the left internal rectus and lower facial muscles; twitching of the eyebrow and wrist muscles; repeated vomiting; slight polyuria, a trace of albumin, and the last two days an irregular, frequent pulse, a temperature of 103°, and stupor. The autopsy showed a tumor within the circle of Willis, immediately in front of the pons, nearly 4 cm. anteroposteriorly, over 2 cm. transversely, and 2 to 3 cm. vertically. It was soft, white, somewhat papillomatous, and, microscopically, apparently an endothelioma. By tearing the rather firm connective-tissue adhesions, the capsule (apparently thickened pia) was separable, except at the corpora albicantia and posterior perforated spaces, and anteriorly where it adhered to the optic nerves, which, with the optic tracts, were much compressed, and the chiasm practically destroyed. The corpora albicantia were not recognizable. The third nerves were pressed outward, the left being bent at a right angle at a point where the facial might well have also been pressed upon.

2. *Sarcoma of the Occipital Lobe:* A clerk, male, aged forty-one years, of tuberculous family, seen April 20, 1902, had had five-weeks' vertigo, followed by frontal (first on right side), and, at times, occipital headache, and of three-weeks' failure of vision. Examination showed double choked disk, a suspicion of weakness on the left side of the face, a little stiffness of the neck; exaggerated knee-jerks, and double ankle clonus. Death resulted June 13. The autopsy showed a soft, reddish-gray mass, 100 mm. anteroposteriorly, 60 mm. transversely, and 55 mm. high, filling the posterior horn of the right lateral ventricle, and infiltrating the white matter on all sides for 15-30 mm. situated chiefly in the occipital lobe and entirely in the white matter, except that it involved the gray matter near the narrow part of the cuneate lobule; the entire thickness of the posterior part of the corpus callosum was involved. The tumor extended to within 25 mm. of the posterior end of the brain, 75 mm. of the anterior, and outward nearly to the gray matter of the parietal lobe, and extended 15 mm. on the side of the descending horn of the ventricle.

3. *Gumma of the Mid-post-central Convolution:* July 31, 1902, a woman, aged thirty-six years, gave a history of marriage at twenty-six; at twenty-seven, a miscarriage at five months; at thirty-one, unconsciousness, fall, and rapid recovery, with recurrences at intervals progressively shortening to about a month; for some time severe nocturnal headaches, partial deafness, forgetfulness, and somnolence. The "spells" began with fifteen to twenty-minutes' headache, sometimes a warning, cyanosis and rigidity; then followed clonus of the left forearm, ending in elevation of the arm over the face, spreading to the left leg, the left side of the face, and sometimes to the right side. The attacks involved vertigo, incontinence of urine and sometimes of fæces, and were followed by sleep and stupidity. Examination showed slight weakness of the left hand (with some astereognosis) and side of the face; a more active left knee-jerk and the Babinski reflex on the left side; and double optic neuritis and a very sluggish pupillary reaction to light. Under increasing doses of potassium iodide, with mercurial inunctions, by August 12 her countenance had brightened very considerably and the headache and stupor had diminished.—*Yale Medical Journal.*

The Ocular Manifestations in Chronic Bright's Disease.—G. E. De Schweinitz states that in general terms it may be said that ocular lesions may occur with any form of nephritis, but there is no question that the various types of retinitis are most frequently associated with chronic interstitial nephritis; that is, with renal sclerosis, whether this is an independent primary affection, or whether it is a sequel of arteriosclerosis. Various types of retinitis and retinal lesions may be symptoms of chronic parenchymatous nephritis. Naturally, the so-called secondary contracted kidney, which is a sequence of the large white kidney, may be associated with retinitis. According to William F. Norris, fully 25 per cent. of the cases of chronic Bright's Disease as they occur in general hospitals are affected by various forms of retinitis. The prognosis *quoad visum* depends entirely upon the character and situation of the exudates, *i. e.* upon the amount of destruction of the percipient elements of the retina. The prognosis *quoad vitam* is bad. The author discusses diseases of the uveal tract in chronic nephritis, nephritic cataract, ocular muscle palsies due to nephritis, and recurring subconjunctival hemorrhages.—*Medicine.*

Report of a Grave Case of Tetanus Treated with Veratrum Viride, with Recovery.—H. B. Sweetser describes his case, and says that in presenting this subject he wishes to emphasize the following points: (1) To put on record a recovery from a severe and grave case of tetanus, under the administration of drugs, the ascertained physiological action of which is directly antagonistic to the action of the tetanus toxins, both poison and antidote affecting in opposite ways the same structures, viz., the anterior horns of the spinal cord. Further than to this extent the treatment was not empirical. (2) To call attention to the fact that chloral is a dangerous drug, which is even more liable to exert its poisonous effects when given during the course of so dangerous a disease than when given in health; and to protest against its reckless and continuous use in cases of tetanus, even after it is plainly evident that it is doing no good. (3) To record the opinion, based on evidence, that some of the deaths ascribed to the tetanus poison have really been due to the effects of the remedies used.—*Northwestern Lancet.*

Cardiac Dilatation at Puberty.—Alfred Friedlander says that the first requisite of treatment of this condition is the removal of the exciting cause, muscular overwork, and this is to be accomplished by putting the child absolutely at rest. To allow the child a "moderate amount" of exercise is hazardous, as his idea of "moderate" is apt to be the simple limit of inclination. If the symptoms be urgent, it is best to insist upon rest in bed, with the child flat on its back for several weeks. The diet should be light and nutritious, but should contain the minimum quantity of fluid, so that the volume of blood to be pumped can be reduced as much as possible. Digitalis is often of value in the beginning, and strychnia at all stages, but it is more important to lessen the work of the heart than to stimulate it. Even after the child is up and about again, all severer forms of exercise must be strictly forbidden. This restriction should last for months.—*Interstate Medical Journal.*

The Action of Strychnine on the Heart, and the Evil of Overdosage.—Roland G. Curtin compares strychnine in its action to electricity. It is a stimulant, and too much stimulation is followed by weakness from exhaustion. The author has never seen a case of marked depression of the heart from chronic disease in an elderly person in which large doses of strychnine were given, and the patient survived. Experience has led him to place the most dependence upon digitalis and alcohol—digitalis, because of its remote as well as its immediate effects; alcohol, because in addition to its being a diffusible stimulant to the circulation, it is, in his opinion, a valuable tissue food. Strychnine fulfills neither of these important offices. It cannot be classed as a food; it will not cause the slow, full, satisfactory ventricular contraction observed after the dose of digitalis.—*The Therapeutic Gazette.*

TENT LIFE FOR THE TUBERCULOUS INSANE.

How to best deal with this class of consumptive is one of the most difficult questions that confronts those in charge of institutions for the insane. The phthisical insane individual differs in many important respects from the ordinary person suffering from tuberculosis, or rather it is his mental alienation that makes him different. The personal habits of those whose minds are unbalanced are almost invariably dirty to a degree, and despite the most careful watching on the part of attendants it is almost impossible to prevent the spread of infection in rooms and wards occupied by the insane. All the most prominent alienists are unanimous in declaring that insane consumptives should be segregated, but the mode of segregation is the crux of the matter.

Dr. A. E. Macdonald, Superintendent of the Manhattan State Hospital, East Ward's Island, New York City, has inaugurated at that large institution a system of tent care of the insane, which, according to Dr. C. Floyd Haviland, one of the assistant physicians, has been attended with the most gratifying results during the year it has been in operation.

On June 5, 1901, forty phthisical patients began a residence in tents. In this number were included all cases of both miliary tuberculosis and phthisis at that time in the hospital. Two large tents were employed, each being fourteen feet high and having a capacity of twenty beds, allowing forty square feet of floor space per bed. These tents were erected upon elevated, dry ground, where they were surrounded by abundant shade, and were constantly swept by breezes from the river. The ground was cleared of all vegetation beneath each tent, and a board floor constructed about eighteen inches above the ground, which being made in sections could be taken up and exposed to direct sunlight as occasion demanded.

In pleasant weather one side of the tent was kept open, so that the interior was literally flooded with pure air, and at all times sufficient ventilation was afforded by large ventilators at either end placed near the top of the tent. Nearby were erected several small auxiliary tents, which included two dining tents, a clothing tent, and those for the residence of the attendants. Facilities for bathing were provided, and a separate water supply was established, while the sanitar arrangements generally and personal cleanliness of the patients were closely looked after.

The results of this method of treatment were most satisfactory. During the year eighty-one patients were given the benefit of tent-life, and in that period of time nineteen deaths occurred among them, a percentage of 23.45 out of the total number of cases treated. On the other hand, when all the deaths occurring in the hospital during the past year are taken into account, these figures make the percentage of those succumbing to tuberculosis as low as 8.8.

The real benefit of the tent system is shown by a comparison of this percentage with that recorded in former years in the Manhattan State Hospital. Ten years ago they formed $17\frac{4}{5}$ per cent. of the total number of deaths, but with increasing care the proportion steadily decreased during the succeeding years, so that the yearly average has been $14\frac{1}{10}$ per cent. during that time. One year ago $9\frac{4}{5}$ per cent. of the deaths resulted from tuberculosis, but under the tent care the percentage of $8\frac{4}{5}$ is established, which is the lowest in the history of the institution

As, however, Dr. Haviland truly says, it is not only the beneficial effect of this treatment to the phthisical patients themselves which should commend its adoption, but beyond that the complete isolation resulting from the method is of particular interest to those concerned in hospitals for the insane, where hundreds of mentally incompetents are so wholly dependent upon their surroundings, and where, in the past, so many have fallen victims to tuberculosis.

Isolation is acknowledged to be the most effective safeguard against spreading the disease in any public institution. In asylums for the insane there is greater need to prevent infection than in ordinary institutions on account of the dirty personal habits of the demented. Therefore, it follows that it is especially necessary to isolate the tuberculous insane.

The tent-care system inaugurated by Dr. Macdonald of the Manhattan State Hospital, although perhaps its trial has not yet been sufficiently lengthy, or on a wide enough scale to admit of the drawing of any definite conclusions, has been thus far so encouraging as to lead to the hope that its extension may be followed by even more satisfactory results.

PLAGUE DISSEMINATION.

MR. FRANK TIDSWELL, M.B. ,etc., Principal Assistant Medical Officer of the Government of New South Wales, read a paper before the British Sanitary Institute on December 12, 1900, dealing with some practical aspects of the plague. Mr. Tidswell in his official capacity had exceptional opportunities of observing the manner in which the disease attacked and spread amongst a white population during the epidemic which prevailed in Sydney.

With regard to the mode of dissemination of plague, the writer is in agreement with the views held by almost all authorities, that rats are the most prominent factors in spreading infection, and he further states that the one clear fact in the Sydney epidemic was that human beings do not become infected directly from one another. No

cases of the disease were observed in which infection could be ascribed to handling or receipt of contaminated articles. The result of the observations at Sydney led to a well-grounded belief that the disease is not spread either directly or indirectly from man to man,

With regard to the natural means by which plague is spread and continued among rats, the evidence offered was not definite. Inoculation did not appear to be a common mode of infection, since true buboes were never found in captured plague rats. This, however, might have been due to the fact that plague is apt to assume a septicæmic form in rats, and hence there would not be a bubo. But swelling of the nearest lymphatic glands, accompanied by hemorrhagic exudation, was usually produced by experimental inoculation, and consequently Mr. Tidswell thought that one would expect it to have been seen if the natural infection had been acquired in a similar way. It was found that rats could be infected by feeding.

The experiments made with respect to fleas as conveyers of plague were for the most part negative, although on one occasion infection was set up by means of an emulsion of flees, taken from a very sick rat captured at an hotel from which had just been taken a girl suffering from plague. The epidemic at Sydney did not furnish any clear evidence on the question of the transference of plague from man to rat.

As to transference from rat to man, the evidence was of a sufficiently convincing nature to induce the Australian observers to believe that rats were the sources of infection for human beings. Regarding the exact manner in which the microbes obtained entrance into the bodies of the victims, the evidence was to the same effect as that obtained elsewhere, namely, that they were infected by inoculation. The preponderance of femoral buboes indicated that the actual site of inoculation was usually somewhere on the lower limbs, but the suggestion of oriental epidemiologists that infection occurs with dust entering small, unnoticed wounds on the bare feet did not apply to the cases at Sydney, as all persons there wear shoes. Nor could any of the patients be supposed to have received the infection through wounds, cuts, or abrasions. Therefore the theory that fleas were responsible for the actual transference of the casual bacteria was the one upon which Mr. Tidswell and colleagues had to fall back. After having exhaustively investigated this matter they became possessed of some facts which seemed to show that Simond's contention that fleas were the conveyers of the plague germ from rat to man was not altogether hypothetical.

The conclusions reached were, that in view of all the evidence—positive as regards rats and fleas, and negative as regards other agencies—they were compelled to believe that the Sydney people were infected by means of plague rats, probably through the intermediation of plague fleas or similar vermin.

One point especially interesting in Mr. Tidswell's paper was that in which he referred to the question as to whether fleas from rats will bite mankind. Galli Valerio has asserted that they will not. Mr. Tidswell is of the opinion that although fleas have a predilection for particular species of animals, they will go upon others, and often sample them by a bite or two before returning to the host best fulfilling their epicurean inclinations. Again, it is said that fleas will remain upon rats until the death of these animals, when the vermin are compelled to seek elsewhere for their sustenance. This statement was borne out at Sydney, as when the rats were dying in immense numbers on the wharves at that place, fleas were so numerous as to be a veritable pest.

The paper quoted from and commented upon was a valuable contribution to the literature dealing with plague, and has thrown some light upon the dissemination of the obscure and loathsome Eastern malady. As, however, has been said on several occasions in the Medical Record, there would seem to be little or no fear of plague gaining a foothold in a country where the sanitary arrangements are good, and where the habits of the people are cleanly. It is pre-eminently a disease of dirt, and cannot flourish except it finds a suitable soil.

THE NEW MATERNITY HOSPITAL.

The Society of the Lying-in Hospital, Second Avenue and Seventeenth Street, has just issued its annual report, which in some respects provides food for serious reflection. It states that the hospital was opened for the admission of patients some eight months ago, since which time 1,278 women have applied for in-door treatment. Owing, however, to scarcity of funds, only one ward of sixty-two beds has been available for this purpose. New York is not by any means too well supplied with institutions of the kind, as, in addition to the society's building, the total capacity of these is something less than 600 beds. If, therefore, the society were able to throw open its entire building, containing 186 beds, the pressure on the other maternity institutions of the city would be greatly relieved, and the poor would be correspondingly benefited.

It is an indisputable fact that the new maternity building is a magnificent structure, fitted with all the latest improvements, and admirably adapted in every way to the object for which it was erected. Nevertheless, it is, under existing circumstances, a white elephant to a great extent, and, unless some public-spirited rich philanthropists should come forward with a sufficiently large endowment fund, must continue to be so. Apparently the wiser plan in the first instance would have been to have expended a smaller sum upon the building itself, but to have assured the maintenance of a certain number of beds. A great part of the splendid building is at the present time useless, because money has not been provided for running expenses. It is always ungracious "to look the gift-horse in the mouth," but in such a case it may be well to give expression to reflections so obvious. The society during the past year, in order to maintain one ward, has expended out of its investment fund the sum of $38,120, while, of course, its opportunities for doing good have been seriously hampered by lack of funds.

The report contains some interesting statistics. For the year ending September 30, 1902, the number of births in the borough of Manhattan, according to the official returns of the Health De-

partment, amounted to 51,668, showing that on an average one child was born every ten minutes. The service of the society during the past year showed a large increase in the number of cases over those attended in the course of the preceding year, the applicants being 4,815, an increase of 1,058. Of this number 878 were admitted into the hospital. The report also states that the average wages received by the husbands in employment was only about $7.26 a week, and the average rent $8.78 per month, leaving a balance of but 68 cents a day to provide each family with food, clothing, and fuel. Great progress has been made with the educational work. Two hundred and nine students and thirty-nine graduates have received instruction, and ninety nurses have taken the usual three-months' course. The total amount of money expended by the society during the year was $78,659.12. Attention is called to the fact that the number of cases treated in the out-door departments of the society was less than a year ago, while the number of applicants was very much larger. This is owing to a lack of means; with the present facilities all the work is being done that can be done. The report lays special stress upon the need of a sufficient endowment to enable its new hospital to perform a vast work of good among the destitute poor of the city.

The publication of the society's report will have the effect, it may be hoped, of inducing some of the many American millionaires to lend a favorable ear to the appeal for help. There could be few better ways of spending money than to enable the society to open the whole of the new maternity building for the benefit of poor and destitute women. At the same time the dilemma in which the society finds itself may serve as a useful object lesson, and tend to drive home the truth that the provision of an ample endowment fund is of as much importance as the erection of an imposing and splendidly-furnished building, whose usefulness is, however, greatly nullified by lack of funds for its maintenance.

The Influence of Preservatives upon the Food Value of Milk.

In bulletin No. 86 of the Maryland Agricultural Experiment Station is the result of investigations undertaken by C. F. Doane and T. M. Price with regard to the above subject.

After referring at some length to the experiments of others as to the influence of preservatives upon the food value of milk, the writers describe experiments which they made with calves at the Maryland Station, and the conclusions reached agreed in the main with those of other investigators. The authors say that it is very hard to draw any definite conclusions looking to the use of preservatives either from the work done at this station or that of other workers. The investigation into the effect of preservatives has given practically the same results in all the trials with mature animals. We find that in the work of Chittenden with dogs and also that of Liebreich with dogs borax and boric acid interfered slightly with the digestion of the food eaten. It is doubtful if this was sufficient by itself to condemn the use of these preservatives except under particular conditions, such as that of illness or infancy. In the trials authorized by the British Commission, neither boric acid nor formaldehyde seemed to have any marked effect on the digestion of the food eaten. In the trials to determine the effect of preservatives on the bodily health, mature animals gained in weight, with a unanimity of results which for the conditions would seem to be conclusive. Both Chittenden and Liebreich found that dogs fed with articles containing borax or boric acid gained steadily in weight and, as far as could be observed, suffered no injury whatever from the preservative. Rabbits and guinea-pigs given borax by Liebreich gained in weight and remained in perfect health. The pigs and children fed boric acid and formaldehyde at the instance of the British Commission suffered no evil result from the preservative, and the pigs made substantial gains. The calves fed for an extended period with milk preserved with boric acid and formaldehyde made very satisfactory gains in weight.

The experiments of Annette with young kittens showed exactly opposite results, as the preservatives were fatal when fed to kittens, which would seem to indicate that the use of preserved milk for children is a risky proceeding.

Thus, nothing has been definitely proven as to the harmful effect of preservatives, but at the same time the wisest course to pursue would seem to be to discourage the use of preservatives in milk in every way possible.

Disease in the Philippine Islands Clinically Resembling Glanders.

Assistant Surgeon R. P. Strong, U.S.A., Director of the Biological Laboratory, Manila, has recently described a disease existing in the Philippines Islands which clinically resembles glanders.

The disease starts as a small nodule situated in the cutis, and frequently in the neighborhood of some slight abrasion. The primary node usually appears upon one of the extremities or in the cervical or abdominal region, but may be situated on the shoulders or chest. From the first nodule the infection spreads apparently along the course of the lymphatics, and eventually many buds form. Frequently the adjacent lymphatics become swollen and arranged in a row, presenting somewhat the appearance of beads on a rosary. The nodules vary in size from about 5 mm. to 3 cm. in diameter. The hair is preserved over the younger tumors, which at first are hard, but usually soften later and form large abscesses. The disease extends gradually, and in neglected cases may spread over almost any part of the body, and even invade the nasal mucosa. A mucous discharge from the nose then appears, and the picture now more closely resembles glanders. The primary nodule, however, has not yet been seen situated in the nares.

The disease runs a chronic course, and may last for months, but the prognosis is usually favorable, and a very large majority of the animals eventually recover. Cattle are sometimes affected with this malady, but it is not so common in these animals as in horses.

Dr. J. G. Slee, veterinarian of the Board of Health, Manila, first called the attention of Dr. Strong to the disease, requesting the examination of several horses afflicted with the glanders. A microscopic study of material removed from the pseudo-farcinous buds revealed the fact that the disease under discussion is of an entirely different origin from glanders, it, not as is the case with glanders, being due to bacterial infection at all, but to a parasite of an entirely different group, namely, one of the budding or yeast fungi.

The disease is not to be confused with that termed

"Bursattee," in India, as described by F. Smith as being due to a "mould fungus," or with that known as "farcin du boeuf." It is, however, probably, very closely related to the variety of lymphangitis epizootica, studied particularly by Fermi and Aruch, and to a similar infection described by Tokishige in Japan. As the organism examined at the Manila laboratory has shown as yet no tendency to ferment sugars, it may be regarded for the present, at least, as a blastomyces.

On the appearance of the first node the hair should be shaved for a considerable distance around it, the nodule opened early, curetted, cauterized, and thoroughly cleansed with some antiseptic solution. As mentioned before, a large majority of the cases eventually recover, although the disease may persist for months.

The Etiology of Cancer.

No disease has been made the subject of so many articles by medical men during the past few years as has cancer. Its etiology has up to the present time baffled the skill and perseverance of the most intellectual and highly-trained scientists of the age, and the mystery of its origin is still but little nearer a final solution. The theories with regard to the cause of cancer are many, but are so well known that it would be supererogatory to mention them.

Dr. Alexander Theodore Brand read a paper before the East Yorkshire branch of British Medical Association entitled "A Contribution to the Etiology of Cancer," in which he gives his reasons for believing that the infection theory of the cause of cancer has much to be advanced in its favor.

That cancer is infectious has long been a belief. In the middle of the seventeenth century Zacutus Lusitanus stated his belief that cancer is contagious, and cited cases. In 1672 Nicolaus Tulpius, the famous anatomist, was so sure of it that he stated that "an ulcerated cancer is just as contagious as an inflammation of the eyes."

The evidence of the exogenesis which strikes Dr. Brand as being of the greatest weight is the fact that cancer once generated spreads locally by affecting its immediate environment, and that it is disseminated metastatically by the blood current and lymph streams, the latter infecting glands en route.

Another very suggestive fact, he thinks, is that while cancer is at the outset a purely local disease, it becomes eventually constitutional, one of the indications of such being the gradual establishment of a so-called "cachexia," and he is further of the opinion that this term "cachexia" simply means that the victim of cancer has become saturated with the toxin of the bacterium causing his disease.

Dr. Brand sums up as follows: "From the evidence at my disposal I deduce that cancer is a specific disease, that it is contagious, and therefore infectious. That there is an infective agent is a logical sequitur.

"Probability and analogy point to this agent being a microphyte and not a microzoön. That this mycrophyte is a facultative aerobic bacterium is suggested by the fact that, though it grows fairly well under free access of air, it grows very much better without it. This is well exemplified by the striking difference in behavior of epithelioma of the lip and of the tongue. Although these parts are very near neighbors, the growth in the one instance is extremely slow, while in the other it is exceedingly rapid. The epithelioma of the lip is exposed to light, to the air, to low temperature, and there is an absence of moisture. The epithelioma of the tongue, on the other hand, is situated in an ideal culture chamber, in the dark, where there are moisture, a fairly constant favorable temperature, and exclusion of air."

The writer concluded his address by declaring that lack of money was one great obstacle to investigation, and said that England should follow the example set by the United States and Germany, in both of which countries large sums of money for the investigation of the cause and nature of this disease had been provided.

Undoubtedly the United States has small reason to fear the rivalry of other countries so far as the investigation of the cause of cancer is concerned, indeed, in some respects she has made more progress in this line of research than some of the majority of the European countries.

The National Health and the British Army.

There has been for a considerable time—and particularly since the outbreak of the South-African War—much discussion among medical men in Great Britain, with regard to the alleged physical deterioration of the inhabitants of the United Kingdom. The rejections of candidates for admission to the army has given rise to a certain amount of alarm. It has been found that more than 50 per cent. of those who have offered themselves for military service, do not fill the exacting requirements demanded of them.

Major-General Sir Frederick Maurice recently delivered a lecture on the subject, in the course of which he said that according to the result of his experience and the inquiries which he had instituted, he had arrived at the conclusion that out of every five men who wished to enlist and primarily offered themselves for enlistment, there were only two remaining in the army as effective soldiers at the end of two years. After alluding to the more frequent assigned causes of physical disability by which it came to pass that under the British voluntary system of enlistment it was only possible to make two soldiers out of every five who offered themselves for military service, General Maurice went on to ask whether this meant that the high proportion of men physically unfit could be attributed to the class from which the bulk of the army was drawn, and, if so, why and how far it was due to remediable causes? So long as there were more young men willing to enlist than were required if they were only fit material for soldiers, it seemed needless or superfluous to talk of conscription or compulsory service. It had to be ascertained, first of all, what was the exact and whole truth in regard to this disability, the conditions and causes which led up to it, and how far these were preventable in their nature. As the question was one of national health, General Maurice recommended that the Royal Colleges of Physicians and Surgeons should thoroughly investigate the matter, and that funds for this purpose should be provided by the Government.

The *Lancet* of November 1, referring to the matter, says that the plan suggested by General Maurice is worthy of adoption. The largest number of rejections, according to the medical report for 1900, were caused by defective development under height, weight, and chest measurement. Among other causes, defective vision was the most frequent; loss or decay of many teeth came next, followed by diseases of the heart and blood vessels, and defects of the lower extremities. Speaking broadly, these are defects of an urban as opposed to a rural and agricultural population, and for the rest they are largely attributable to preventable causes, such as defective hygiene or

improper feeding, overcrowding, and defective ventilation. The statement that the British race has deteriorated, applies only to those who live in cities, but as the urban population is at the present time much greater than the rural, and is increasing at a rapid rate, the matter is a serious one.

Transportation in New York.

The means of transportation in New York are entirely inadequate to the needs of its population. This fact has been clearly recognized for a considerable period, and from time to time an individual has given voice to public sentiment on the subject. But the mass of the people have exhibited an extraordinary indifference in the matter, and there has been no concerted movement with a view to better the situation, or to probe into the causes of the lamentable lack of accommodation provided by the corporations which control the street and elevated railway roads of the city. The majority of New York citizens appear to regard any attempt to remedy the present state of affairs as hopeless, and as beyond the reach of practical politics.

Recently, however, some prominent women of the community, aroused by the excessive overcrowding of cars—which naturally affects members of their sex far more unpleasantly than men—have entered a vigorous protest against the continuance of existing conditions of transportation in New York. The question has also been taken up by the Merchants' Association of New York, and a manifesto has been issued by its Committee on Franchises and Transportation.

In this appeal to the public the matter is viewed more especially from the standpoint of outraged decency and menaced public morality. From this point of view there is, undoubtedly, much to be said, and a sensitive woman who is compelled to use street or elevated cars, when the traffic is at its height, must receive some severe shocks to her modesty, as well as suffering great inconvenience. The overcrowding is the chief charge that must be brought against the public railway system of New York, for with the removal or even the alleviation of this condition, not only would the cause of decency be benefited, but the principal menace to health would be banished. In the Medical Record, December 9, 1899, appeared an editorial, in which many of the objections to the present methods of conducting the transportation service of New York were dealt with, and it was then urged that the matter should be looked into, and that efforts should be put forth, to endeavor to ameliorate as far as was possible the obnoxious features of the system. In the course of the article referred to, it was pointed out that so long as the excessive overcrowding was permitted, no effectual measures could be contrived to bring about really satisfactory reforms in street transportation, but that, at the same time, if more attention were paid to some important and obvious details, the lot of the passenger would be, to some extent, rendered more bearable. It was shown, for instance, that there was room for considerable improvement in the system of ventilation of street cars, and that there should be no need to open windows for this purpose, but that these should be kept tightly closed, and ventilation effected from the top. It was argued that doors should not be open, except when required to admit or let out a passenger, and, in particular, that the doors at the end near the motorman should be kept shut always. Since the writing of the article in question, there has been no improvement whatever in the management of the street-car service; overcrowding is as bad as ever, and as a mode of travel the car lines and elevated railway provide as unhealthy, and in every way as unpleasant a one as can well be imagined.

The appeal of the Merchants' Association should strike home to all the inhabitants of New York, for reasons of health and for reasons of morality. Those in control of the transportation system of the city have been too long permitted to ignore the rights of the public by their failure to provide the necessary facilities for traveling in comfort and decency, and with due regard to the health of their patrons. A thorough ventilation of the subject in the lay and medical press, and the pressure of public opinion induced thereby, should go far toward bringing about the much-needed reforms.

Lemon-juice as a Bactericide.

The daily press is just now much interested in exploiting a statement from Dr. Asa Ferguson of London that lemon-juice kills the typhoid bacillus in drinking water. Although it has long been known that citric acid is a powerful germicide, Dr. Ferguson is apparently the first one to popularize lemonade on such a basis. The wholesale and effective manner in which a teaspoonful of lemon-juice will destroy the pathogenic microorganisms in a glass of water is certainly astonishing if not spectacular. It is from both of these points of view that the experiment appeals to the public. The Chicago Board of Health hastens in its disinterested and public-spirited way to confirm the conclusion, and the boon is launched accordingly. Something more than this confirmation will be needed by the profession before the adaptability of this wonderful discovery can be demonstrated. If in the end, however, it can be proven that lemon-juice or citric acid can do all that has been promised, Dr. Ferguson will deserve all due credit for practically applying a new principle of typhoid prevention. In the meantime it may be somewhat comforting for the people to believe that they are protected from infection by the use of this new drink, but it is hardly fair to encourage them to feel any safety against the infected oyster merely because a few drops of lemon-juice are sprinkled over its surface.

An International Congress of Thalassotherapy.—In 1894 the first International Congress of Thallassotherapy was held at Boulogne-sur-Mer, France, and the second congress was held the following year at Ostende. Since that date no general assembly of medical men especially interested in this branch of therapeutics has been held. It has been determined, however, to revive the organization, and the announcement is made that the third congress will be held at Biarritz on April 19-21, 1903. The following are the subjects for set discussions at this Congress: (1) "What Is the Effect upon the Processes of Metabolism of a Sojourn at the Seashore?" (2) "What Are the Effects of Marine Therapy as Regards the Generalization of Tuberculosis?" (3) "What is the Influence upon the Cardiovascular Apparatus of a Stay at the Seashore and of Thalassotherapy in General?" Membership in the Congress is open to all interested in the subject of marine therapy who register and pay a subscription of ten francs. The latter may be sent to the treasurer, M. Raynaud of Biarritz. Further information may be obtained by addressing the foreign secretary Dr. J. Seguel, 68 Boulevard Malesherbes, Paris.

News of the Week.

A Lister Jubilee.—The issue of the *British Medical Journal* of December 13, 1902, is dedicated to Lord Lister in celebration of the fiftieth anniversary of his admission to the medical profession. It contains the following articles: "Remarks on Plugging with Iodoform Gauze in Operations Performed in Cavities of the Body," by Professor Ernst Bergmann; "An Essay on Scientific Surgery, the Antiseptic Method of Lister in the Present and in the Future," by Dr. Lucas Championniere; "Observations on Certain Cerebral Localizations," by Prof. Francesco Durante; "A Clinical Lecture on the Antiseptic Treatment of Wounds—The Antiseptic Treatment in Denmark," by Prof. Oscar Bloch; "Contribution to the Treatment of Fractured Patella," by Professor Mikulicz-Radecki; "The Bradshaw Lecture on Infective Arthritis," by Howard Marsh; "Remarks on the Influence of Lister upon Military Surgery," by Alexander Ogston; "An Address on Pasteur and Lister," by D. Berry Hart; "Lord Lister and Antiseptic Surgery—The History of a Revolution—Early Days in Edinburgh," by Thomas Annandale; "Lord Lister and the Evolution of Modern Surgery," by Sir Hector C. Cameron; "Edinburgh Royal Infirmary," by John Chiene; "Listerism and the Development of Operative Surgery," by W. Watson Cheyne. In the closing article, entitled "Recent Years, a Bibliography," Professor Chiene gives an interesting and appreciative sketch of the greatest life-saver of the nineteenth century. No living man, the writer said, has done so much to advance scientific medicine as Lord Lister. He studied in his early work the essential nature and causes of inflammation and suppuration in wounds. He was most enthusiastic in his investigations. He began to experiment with carbolic acid in the treatment of compound fractures, which had always before presented such terrors to the surgeon, abscesses, and the ligature of arteries. He used carbolized gauze, oil-silk protective, carbolic spray, etc., but he continually sought for improvements. He aimed at the simplest methods, and the avoidance of irritation of the wounds by the antiseptics used. He experimented largely with corrosive sublimate. He finally made the dressing-gauze impregnated with the double cyanide of mercury and zinc. After a while he reserved the use of carbolic acid for disinfecting skin and instruments. He abandoned the carbolic spray when it was proved ineffectual. He was constantly seeking for improved methods.

Prof. George E. Post of Beyrout, Syria, President and Professor of Surgery of the American College of that place, while on a short visit to his relatives in this country, has been the recipient of many well-deserved courtesies from his numerous professional friends in Washington, Philadelphia, Boston, and this city. Abundant opportunities have been afforded him by the leading surgeons to witness operations in the larger hospitals and compare experiences in the leading lines of modern surgical work. On Saturday evening last a private complimentary dinner was given him in this city, at which were present several of the leading lights in the profession. The RECORD also tenders Professor Post—one of its life-long subscribers—its best compliments and heartiest good wishes.

Gift to a London Hospital.—Mr. William Waldorf Astor has given £50,000 to the Hospital for Sick Children in Great Ormond street to build a new out-patient department. The building will be dedicated to the memory of Mr. Astor's young daughter Gwendoline, who died recently.

Discouraging the Immigration of Consumptives.—A committee appointed by the California State Senate to investigate the conditions connected with the migration of consumptives to California from eastern States, and the proposed plan to establish a state institution for the care of such patients, has decided to recommend to the legislature that legislation looking to the restriction of this travel been acted. It was decided not to support the plan of establishing a home for patients of that class, the committee being of the opinion that such a move would result only in encouraging persons suffering with tuberculosis to go to California.

Parents May Let Their Children Die.—The Supreme Court of Georgia has handed down a decision which the advocates of Christian Science regard as a victory for them. The decision holds that parents are not compelled to give medicine to their minor children when they become ill and that failure or refusal to give medicine to these children is not a violation of the laws of the State. A Christian Scientist, named Justice, refused to give medicine to one of his children when it became ill and refused to allow a physician to attend the child. After an illness of several days the child died. The neighbors of Justice swore out a warrant for him charging him with failure to provide the necessary sustenance to the child, a crime under the laws of the State of Georgia. This was the only charge upon which they could prosecute. The case was tried in the City Court of Dublin, where the man lived, and he was fined $300. He appealed the case from one court to another until it reached the Supreme Court, which reversed the decision of the lower courts.

A Sanatorium for Consumptives near New Haven.—Several gifts have recently been made to the New Haven County (Conn.) Anti-Tuberculosis Association, which will render possible the erection of a sanatorium. It is planned to build on Woodbridge Heights, several miles north of New Haven, and on some of the highest ground in Connecticut, a complete modern tuberculosis hospital, which will be run on the fresh air system. Three cottages of eight rooms each, will be built at once, and it is hoped to have the institution open for the reception of patients inside of a twelvemonth. It is hoped to demonstrate by the results of treatment in this sanatorium that tuberculosis can be as successfully managed in the drier altitudes of Connecticut as in the Adirondack region in New York State or in Colorado.

Courses in Hygiene at the Teachers' College.—When the new building, to contain a gymnasium and laboratories, is ready, instruction will be given at the Teachers' College of Columbia University in psychology, child study, physiology, bacteriology, gymnastics, hygiene, education, the theory and practice of teaching, physical education in escondary schools, the history of physical education and anthropometry. The full course will occupy two years. The new department will be in charge of Dr. T. D. Wood.

A Convalescent Hospital on Blackwell's Island.—Plans have been filed for alterations to the old Amusement Hall on Blackwell's Island, opposite the Metropolitan Hospital. After the alterations are completed the building will be used as a convalescent hospital.

Foot-and-Mouth Disease.—Connecticut is believed to be now entirely free from foot-and mouth disease, and it is thought that the quarantine against cattle from that State will soon be raised. Governor Odell of New York has protested against the raising of the quarantine, but Secretary of Agriculture Wilson holds there will be no danger to this State in so doing, since federal quarantine will remain on Vermont, Massa-

chusetts, and Rhode Island, and the State of Connecticut has also rigid quarantine against Massachusetts and Rhode Island. Over a thousand cattle in New England have been slaughtered and cremated on account of the disease, and of this number nearly 800 were in Massachusetts.

The Virginia Conference of Charities and Correction.—The next meeting of this association will be held in Richmond, February 10, 11 and 12, 1903, under the presidency of Robert Gilliam of Petersburg. The subjects for addresses, papers, reports, and discussions at the approaching meeting are: "Charitable and Penal Institutions of the Counties," "Shall Virginia Have a State Board of Charities?" "State Care of the Feebleminded," "Juvenile Courts and Reformatories," "County Poor Houses." Prominent persons connected with charity organizations in other States will be present to make addresses and to participate in the discussions. Those wishing to become members should send their names to the secretary, George B. Davis of Richmond. The conference was organized in 1900, and chartered the following year.

Announcement of the Edward N. Gibbs Memorial Prize.—The New York Academy of Medicine announces that the sum of one thousand dollars will be awarded to the author of the best essay, in competition for the above-mentioned prize, on "The Etiology, Pathology, and Treatment of the Diseases of the Kidney." Essays must be presented on or before October 1, 1904. Each essay must be in English, typewritten, designated by a motto or device, and accompanied by a sealed envelope, bearing the same motto or device, which shall contain the name and address of the author. No envelope will be opened except that which accompanied the successful essay. The academy reserves the right, according to the direction of the donors, not to award the prize if no essay shall be deemed worthy of it. The academy will return the unsuccessful essays, if claimed by their respective authors, or by authorized agents, within six months. An essay must show originality in order to obtain the prize. The competition is open to the members of the regular medical profession of the United States. The original of the successful essay shall be the property of the academy, and, according to the deed of gift, will be published in its transactions. The essays must be sent to the Committee of the Trustees of the New York Academy of Medicine on the Edward N. Gibbs Memorial Prize.

Obituary Notes.—Dr. Alexander Denby died on December 18 in St. John's Hospital, Brooklyn, twenty-four hours after arriving there for an operation for appendicitis. He was stricken with typhoid fever five weeks ago, and the second disease manifested itself recently. He was born in St. Petersburg twenty-four years ago, and he was graduated from the Long Island College Hospital in 1899.

Dr. Frederick L. Brady, who was a member of Troop B of Roosevelt's Rough Riders during the Spanish-American war, died in St. Luke's Hospital from typhoid fever on Christmas Eve. Dr. Brady was thirty years old, and was a graduate of the College of Physicians and Surgeons of this city in 1899. During the Spanish-American war, as a member of the Rough Riders, he was in the engagement at Las Guasimas, the battle of San Juan Hill, and the siege of Santiago.

Professor R. v. Krafft-Ebing, the well-known neurologist and alienist of Vienna, died the week before Christmas at Graz, in Styria. He was born August 14, 1840, and was professor of psychology and nervous diseases at the University of Vienna.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LADY DUDLEY'S CASE—SIR W. WHITLOO'S GIFT—LORD LISTER'S JUBILEE—X-RAYS IN CANCER AND RODENT ULCER—DYSMENORRHŒA—OBITUARY NOTES—DR. OLDHAM'S WILL.

London, December 12, 1902.

The sudden illness of the Countess of Dudley has caused deep regret and some surprise in Dublin, and much sympathy is expressed for the Lord Lieutenant throughout the country. Her Excellency returned on Thursday from Belfast after the Viceregal visit, opened a sale of works for the Royal Hospital for Incurables on Friday afternoon and seemed in her usual health. On Sunday afternoon she was seized with appendicitis, and the condition was so acute that early on Monday morning an operation was performed by Mr. C. B. Ball.

A bulletin was issued at 8.30, signed by Walter E. Smith, E. H. Bennet, C. B. Ball, W. J. Smyly, and announced that Sir F. Treves was expected in the afternoon.

The progress of the case has been normal, and at the hour of my despatch the condition of the patient is pronounced satisfactory.

It was only at the close of November that Her Excellency, accompanied the Lord Lieutenant to Belfast to open a splendid medical institute presented by Sir Wm. Whitloo.

The Bradshaw Lecture at the Royal College of Surgeons was delivered on Wednesday by Mr. Howard Marsh on Infective Arthritis. Before entering on his subject he drew attention to the fact that the day before was the jubilee of Lord Lister's reception as a fellow of the college, and what his name has since become is everywhere the occasion of admiration and gratitude. "The poet alluded in trenchant phrase to those who shut the gates of mercy on mankind, Lord Lister has done more than any living man to throw them open." He then said that though Lister had never sought honors, they had flowed upon him from all directions, and his cup must have been full when he saw his principles succeed in one of the most dramatic events in history, the rescue of the King from imminent peril.

The effects of *x*-rays on cancer and on rodent ulcer were brought before the Pathological Society in two communications. The first was by Mr. Shattock, who had had the opportunity of studying a specimen which was excised by Mr. Brook. The tumor had been treated by *x*-rays for about three months, and clinically seemed to have decreased in size, and become more movable on the subjacent parts. Nevertheless, after removal, no change was found which could be referred to the treatment. At no part of the margin was the growth ceasing to extend. No degeneration, no cytolysis had been induced. The diminution in size and loosening of deep connections were difficult to explain, but it was suggested that they might be due to the disappearance of a subinflammatory œdema.

The second communication was by Mr. Stephen Mayou, who thought the effects of *x*-rays closely resembled those of other stimuli. Though painless when applied to healthy tissues, they produced a superficial inflammation, which was aggravated by other stimuli—a fact which is perhaps not so generally recognized as it should be. The dilatation of vessels seemed in some cases to be permanent after prolonged exposures. He reported a case of rodent ulcer completely cured by the rays. He thought the rodent cells themselves acted as irritants and exhibited sections to show that the leucocytosis was around these cells more than the neighboring tissues. The nodular masses disappeared by sloughing, but the outlying masses of rodent cells degenerated from without inward. Mr. Mayou also mentioned two cases of mammary cancer treated by *x*-rays. One he considered cured, the other not benefited.

A practical discussion on dysmenorrhœa took place at the Obstetrical Society. It originated in a number of cases cured by dilatation of the cervix reported by Drs. Herman and Andrews and compared with others not benefited. They did not consider the curable cases were associated with imperfect development, but in about two-thirds of the cases it begins with the establishment of menstruation, and comes on later in about one-third. Almost always it begins before the age of twenty-five years. They did not find treatment affected by the age, or by the duration of the affection or of married life. In cases cured by dilatation the pain usually began with the flow; in those not thus curable, two days before. Pain lasts about two days in the curable and twice as long in those not curable by dilatation. The pain is paroxysmal in four-fifths of those amenable to the treatment; it is constant in three-fourths of those not. Only a few patients

passed membranes. There was no evidence of such narrowing of the canal as would obstruct the flow.

The President, Dr. Horrocks, thought it was generally agreed that dilatation would relieve intermittent pain, and that pointed to a uterine origin. The worst forms were ovarian, and then the pain was mostly constant, though there were exceptions. He mentioned a case with no vagina and scarcely a rudiment of a uterus which was only cured by removal of the ovaries. Had there been a uterus he should have ascribed the pain to it. He held that dilatation and slitting of the cervix ought always to be tried before more severe measures. Another case of imperfect development was mentioned by Dr. Boxall. With a very undeveloped uterus and vagina there were no ovaries, but on opening the abdomen rudimentary testes were found, so the wound was closed. The pain did not recur.

Dr. Heywood Smith said splitting the external os was useless—in fact, produced the condition which trachelorrhaphy was devised to remedy. The internal os must be divided.

Dr. Arthur Giles said that when the pain preceded the flow it was congestive, and therefore dilatation was not likely to be useful. The cause of painful contractions was obscure; to understand it we need to know why the contractions in labor are painful.

Dr. Galabin said the so-called spasms often lasted a long time. Dr. Lewers said dilatation did not begin until resistance was overcome. Dr. Griffith had often demonstrated a normal canal behind a "pin-hole" os. Dr. Briggs confirmed the value of incision. Dr. Herman replied on the points raised.

Mr. Manley Sims, F.R.C.S., died on Tuesday in his sixty-second year. He for many years enjoyed an extensive practice among the upper classes.

The death is also announced of another nonagenarian —Mr. E. H. Berry, M.R.C.S., in his ninety-second year. Also of Dr. J. Stewart Kilgour, aged eighty-seven years.

The will of Dr. Henry Oldham, formerly obstetric physician to Guy's Hospital, and whose death I recently mentioned, has been proved for £203,000, and it states that he had previously amply provided for his eldest son. This amount is therefore divided for the most part among his other children and his grandchildren.

OUR PARIS LETTER

(From Our Special Correspondent.)

BACCELLI'S TREATMENT OF TETANUS USED IN FRANCE—BABINSKI ON HEREDITARY LOCOMOTOR ATAXIA—COMBY'S TREATMENT OF TUBERCULOUS PERITONITIS—DR. VALLAS' REPORT AT THE CONGRESS OF SURGERY ON THE TREATMENT OF TETANUS.

PARIS, December 12, 1902.

At a recent meeting of the Medical Society of the Paris Hospital, Dr. Henry Claude gave the history of a case of tetanus in which he used injections of carbolic acid as recommended by Baccelli. The patient was a man, forty-six years old, with a superficial wound of the left little finger. Five days after, the symptoms of lockjaw were apparent, and were characterized by intense general contracture with paroxysms, dysphagia, fever, and delirium. An injection of 20 c.c. of antitetanic serum was made the first day, and afterward injections of 20 cgs. of carbolic acid were made daily with venesection and subcutaneous injections of saline solution. Chloral was also given in large doses, and the finger was amputated. Toward the eighteenth day the patient improved, the fever fell, and the perspiration and quantity of urine excreted increased noticeably. It is impossible to feel sure that the cure was due to the carbolic acid, still it would seem to have been useful, if one considers the uncertain results produced by the other agents employed. Hereditary locomotor ataxia of syphilitic origin is, according to the well-known neurologist, Dr. Babinski, more frequent than is imagined. He has seen several case, of this, and presented to the society two patients who showed symptoms of hereditary locomotor ataxia. The first is a young woman, twenty-two years old, with Hutchinson's teeth, who had anal ulcerations at the time of her birth. For about two years she has had lancinating pains, the reflex of the pupils is abolished, and the left patellar reflex is weaker than the right. The father of this young woman contracted syphilis while his wife was pregnant and infected her. He is himself afflicted with tabes dorsalis. Another patient shown by Dr. Babinski is fifteen years old. Her pupils do not react to light, the patellar reflex is abolished, there are urinary disturbances, lymphocytosis of the cephalorachidian liquid, left choroiditis of a specific nature, and mental disturbances showing a tendency to dementia or diffuse meningoencephalitis. Her father shows symptoms of tabes, such as absence of the patellar reflex, Argyll-Robertson's sign, and gastric disturbances. This patient was not aware he was suffering from tabes, and his physicians had not found locomotor ataxia. Dr. Louques was also able to describe the condition of a family where the father died of progressive general paralysis in an asylum, and the mother and two daughters show symptoms of tabes. In an article published recently by Dr. Comley in the *Archives of Pediatrics*, the author claims that a great number of cases of tuberculous peritonitis may be cured by medical treatment. Absolute rest in bed he considers a most important part of the treatment. Plenty of air and sunlight should also be insisted on. The child should be sent to the seaside whenever it is possible to do so, or at least into the country. The diet should consist of milk, eggs, mashed vegetables, meat, raw meat, or the juice extracted from the latter. Cod-liver oil, with or without creosote, glycerophosphate of calcium, lecithine, inunctions of iodine on the abdomen, collodion, and compression of the abdomen are good therapeutical measures, but quite accessory.

At the meeting of the Congress of Surgery, held on October 24, Dr. Vallas of Lyons read a long report on the treatment of tetanus, in which he reviewed the whole question and indicated the results obtained. There are three methods of treatment: the old routine treatment, the serum treatment, and the treatment of Baccelli by injections of carbolic acid. The first included complete isolation and silence about the patient, and the use of chloral in large doses, as much as 10 to 12 gms. being given daily. As for removing the focus of infection by amputation, the latter would be only justifiable when the condition of the limb might favor such a decision. The serum treatment was discovered by Behring and Kitasato in 1890. The serum is not antitetanic but antitoxic, as it does not detroy the microbes of tetanus, a fact which shows the importance of treating the wound most energetically. Nocard's experiments in 1895 carried out on animals exposed to tetanus showed how useful the serum was as a preventive. Whereas not one of 375 animals injected was affected by tetanus, fifty-five cases were seen in other animals. In 1897 Nocard repeated this experiment; 2,727 horses were injected, and not one was affected with lockjaw, whereas 259 cases of this disease were seen at the same time.

Dr. Bazy was able to stop at Bicetre an epidemic of lockjaw by having preventive injections carried out. According to Dr. Vallas, whenever a wound is of a suspicious nature, an injection of 10 c.c. should be made the first day, the same amount the third and the tenth day. In case the wound is not yet healed, the injection should be repeated every fifteen days. As a treatment of lockjaw, subcutaneous injections would not seem to be always efficacious. Dr. Vallas has collected 373 cases with the following results:

Incubation of 10 days: 141 cases, 80 deaths, 57 per cent.; incubation of more than 10 days, 118 cases, 24 deaths, 20 per cent.; incubation not determined, 114 cases, 41 deaths, 35 per cent., which makes a total of 373 cases with 145 deaths, or 39 per cent. Lockjaw in infants (15 cases with 11 deaths), and during the puerperium (15 cases with 12 deaths) is always most pernicious. The mortality in former times being 70 per cent., it may be said that there has been some improvement under this new treatment. The amount to be injected at first is about 30 to 40 gms., to be repeated at least every day until there is a change for the better, when the amount may be diminished. Some patients take as much as 300 or 400 gms. of serum. In one case a negro had 1,800 gms. injected.

Intravenous injections have also been used, and seem quite rational and without danger. The serum should be diluted in about 500 gms. of saline solution. Out of 31 cases treated in this manner, there were 13 deaths, or 42 per cent. of mortality. Intracerebral injections have not given good results and should be rejected, as they are apt to cause most serious accidents. Baccelli's method consists in the injection of a 2 to 3-per-cent. solution of carbolic acid. Sometimes a 10-per-cent. oil solution is employed. About 30 to 40 cgs. of carbolic acid should be injected daily. Out of 80 cases treated in this manner, there were only 8 deaths. It should be remembered, however, that experiments have shown that it is not a specific, and, moreover, tetanus would seem to be less deadly in Italy. The treatment by opotherapy, as formulated by Wassermann and Takaki, does not seem to be justified by the experiments which have been carried out. Subcutaneous injections of hydrogen peroxide have been tried with success in three cases on the horse, and intravenous injections of an iodide solution have succeeded in two cases. Persulphate of sodium has been successful in the hands of Gelibert and Tenillade in three cases.

Dr. Vallas concludes as follows: Whenever there seems to be some doubt about the cleanliness of a wound, preventive injections should be made. All cases of

tetanus should be treated by subcutaneous injections of serum, the latter treatment being reinforced by the use of chloral and carbolic acid.

Dr. Lucas Championnière of Paris said he considered the intracerebral hemorrhages quite without danger, and would willingly employ them in serious cases. As for amputation, he had found it quite useless. The preventive treatment had been most efficacious when an epidemic of tetanus broke out in his service some years ago. Dr. Girard of Berne said he thought intracerebral injections should not be condemned. There is some danger in using them when the injection does not penetrate into the ventricle, but, on the other hand, this treatment seems to act when the ordinary injections have failed. Dr. Mannoury of Chartres is also of the same opinion, as well as Dr. Barette of Caen, who has used this method four times with two cures. Dr. Reboul of Nimes said that he used to see 4 to 5 cases of tetanus yearly until 1897. Since then he had made preventive injections of serum and had only lost two patients who had not been injected. Dr. Schwartz of Paris insisted on the importance of making preventive injections. From 1890 to 1898 Dr. Schwartz had seen 315 suspicious wounds in his service, and lockjaw had come on in 8 cases with 6 deaths. Since 1898 Dr. Schwartz had seen 300 cases of wounds received in the street, and there had been only two cases of tetanus—one in a patient who came in with symptoms of lockjaw, and another in one who had not received any injections.

THE ALLEGED PARASITE OF YELLOW FEVER.

To the Editor of the Medical Record:

Sir: I read two days ago, in your issue of December 13, an editorial entitled "The Alleged Parasite of Yellow Fever," in which you refer to the small hyaline bodies found in the blood of yellow fever patients and subsequently in that of healthy individuals. Permit me to offer the suggestion that these bodies were described by the late Major Walter Reed, Surgeon, U. S. Army, in the *Journal of Experimental Medicine*, Vol. II, No. 5, issued in September, 1897. They were described by him as small granular amœboid bodies, one-third to one-half the diameter of a red blood cell. As I had the good fortune to participate in this work of Major Reed's in the examination of the blood of healthy and vaccinated children, calves and monkeys, I am in a position to state that the amœboid movement consisted in the projection and withdrawal of blunt pseudopodia; there was seldom, if ever, any change in their relative position. The amount of pale transparent ectoplasm was so small that when the bodies became quiescent it was no longer visible. We often encountered them in our examinations of fresh blood from yellow fever patients at Havana, but as they were already familiar to us we gave them no further consideration. The blood of all our cases was carefully studied in both fresh and dried preparations.

I have seen these bodies so frequently that I regard them as constituents of normal human blood, but they may be increased in number in various pathological conditions. Within the past year an eminent American authority, who is thoroughly familiar with them, has expressed the opinion to me that they are amœboid blood plaques.

To those interested the plates from photomicrographs published with the paper mentioned above will serve better than any detailed description.

James Carroll,
1st Lieut. and Asst. Surgeon, U. S. Army.

THE IMMIGRATION BILL AND FALSE MEDICAL CERTIFICATION.

To the Editor of the Medical Record:

Sir: At page 983 of your number of December 20 it is stated that amongst the amendments to the proposed new immigration bill suggested by me was one which "was to punish for perjury physicians who certify to the good health of immigrants who are found afflicted with disease." From the words thus quoted it is not clear to what physicians I have reference, and in order that no one may think that I intend to refer to the surgeons of the United States Marine-Hospital Service or to any other surgeons representing the Government I desire to state that I had solely in mind the physicians on several of the incoming steamers who do not hesitate to swear on the manifest that the health and physical condition of the various immigrants are "good," "perfect," etc., in cases in which the United States examining surgeons find without the slightest difficulty that such immigrants are afflicted with loathsome or contagious diseases, more particularly, favus and trachoma. Outrageous instances of the sort have occurred during the short period that has elapsed since I took office. Only last week a man's mental condition was sworn to as being "good," when our surgeons determined that he was an idiot; and any layman could see at a glance that his mental condition was unsound. I write this letter at the instance of the United States medical staff at this station.

Wm. Williams, Commissioner of Immigration.

New York, December 27, 1902.

Book Reviews.

A Reference Handbook of the Medical Sciences. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. A New Edition, Completely Revised and Rewritten. Edited by Albert H. Buck, M.D., New York City. Volume V. New York: Wm. Wood and Company, 1902.

The first article in this volume is on inflammation, and is illustrated by some exceedingly clear and handsome plates; the last article is on mosquitos, and is freely illustrated by wood engravings. These are an epitome of the volume, which contains articles on every conceivable subject falling alphabetically between these two titles, illustrated by 576 half-tone and wood engravings and eleven full-page plates. Among the more important of these articles are influenza, insanity (125 pages), insects, intestines, intubation, iritis, jaws, joints (40 pages), kidneys (55 pages), labor, larynx (50 pages), leprosy, leukæmia, liver (40 pages), lungs (45 pages), lymphatic system (45 pages), malarial diseases, Manila and the Philippines, mastoid operations, mercury, metabolism, military hygiene (25 pages), milk (25 pages), and mineral springs and waters. The number of contributors is 149.

It is impossible to do justice to a work such as this without entering upon a particular review of the individual articles, which would lead us far beyond the limits of a book notice. We can only repeat what we have said in substance before, that this enclycopedia is without an equal in the world of medical literature, not only in the range of topics presented, but also in their treatment and in the wealth of illustrations employed in their elucidation. There are few subjects connected in any way even remotely with medicine which are not here explained in all necessary completeness.

Diseases of the Bronchi, Lungs, and Pleura. By Prof. Dr. Frederick A. Hoffmann, Professor of Medicine in the University of Leipzig, Prof. Dr. O. Rosenbach of the University of Breslau, and Dr. E. Aufrecht, Chief of Clinical Medicine in the Magdeburg-Altstadt City Hospital. Edited with Additions by John H. Musser, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Authorized Translation from the German, under the Editorial Supervision of Alfred Stengel, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Fourth Volume in the Series of Nothnagel's Practice, American Edition. Philadelphia and London: W. B. Saunders & Co., 1902.

The American edition of this excellent practice of medicine follows closely the original German, but it has some added features for which Dr. Musser is responsible. Among these are the latest facts concerning the anatomy and physiology of the bronchi, foreign bodies in the tubes, the pathology, bacteriology, and treatment of bronchitis, fibrinous bronchitis, and eosinophilia in asthma. The present volume does not include the articles on tuberculosis, which are reserved for a future book. All the articles are complete, being, in fact, a series of monographs by those qualified to speak upon the subjects assigned them. The chapters on treatment are quite like those of the usual German textbook, and many commonly-accepted methods in therapy are abandoned for newer and presumably more efficient procedures. Hydrotherapy, pneumatic cabinets, pulmonary gymnastics, and similar methods are given a prominence which should have its effect in at least subjecting these methods to a searching trial. Alcohol and digitalis are not praised in the treatment of croupous pneumonia, while quinine regains some of its lost prestige.

Malarial Fever—Its Cause, Prevention, and Treatment. By Ronald Ross, F.R.C.S., D.P.H., F.R.S. Walter Myers, Lecturer, Liverpool School of Tropical Medicine. Ninth Edition. New York, London, and Bombay: Longmans, Green & Co., 1902.

The author of this modest book, whose name is so well known in connection with the mosquito as a factor in malaria, published his observations only a few years ago under the auspices of the Liverpool School of Tropical Medicine. Since that time a complete revolution in the theory of malarial propagation has taken place, mainly due

to his studies. The fifth edition is a complete exposition of his views on the subject, and includes, besides, an account of his very interesting studies of the insect in question, and some very useful notes regarding the treatment and prevention of the disease for medical and popular reading.

Textbook of Medical Jurisprudence and Toxicology. By John J. Reese, M.D., late Professor of Medical Jurisprudence and Toxicology, University of Pennsylvania. Sixth Edition. Revised by Henry Leffmann, A.M., M.D., Professor of Chemistry and Toxicology, Woman's College. 12mo., pp. 660. Philadelphia: P. Blakiston's Sons & Co., 1902.

This well-known and excellent work has received a thorough revision by the editor, and is now fully up to the requirements of the present-day science of jurisprudence. The numerous new poisons receive their share of attention, and many of their more modern antidotes are fully discussed. To such students of legal medicine as require a condensed and thoroughly practical view of the subject, this book is well able to carry its own recommendation.

Textbook of Anatomy. Edited by D. J. Cunningham, F.R.S., M.D. (Edinburgh and Dublin), Professor of Anatomy and Chirurgery, Trinity College, Dublin. 8vo., pp. 1,309. New York: The Macmillan Co.; Edinburgh and London: Young J. Pentland, 1902.

The methods of teaching anatomy have so much improved during the past few years that works similar to the one in hand have been necessary to meet the wide demand for the more accurate and practical applications of this fundamental branch of medical and surgical study. In keeping also with the requirements of the times, numerous collaborators have been enlisted in a common cause, each vying with his colleague in bringing his particular work up to the greatest degree of accurate detail. In such respects the book is a great success, and contains as much originality of arrangement and as much novelty in treatment as could be expected in dealing with purely descriptive facts of structure. The general arrangement of subjects is a natural one, and enables the student to build his foundation as he goes. After an introductory chapter on embryology, in which the animal cell is traced in all its intricate series of evolutionary changes to the fully-developed fœtus, there follows the chapters on osteology, and articulations of joints, and then, in turn, those on the muscular, nervous, vascular, respiratory, digestive, and urogenital systems, with separate chapters, also, on the organs of sense and the integument, on the ductless glands, and on surface and surgical anatomy. It is, however, in the detail treatment of these different subjects that the work of the various contributors merits the highest commendation. Most admirable, also, are the illustrations, which are all new, and made especially for the volume. The aim of the various authors has been to give a perfectly clear picture of a given part in all its artistic proportions and relations, and in this they have succeeded far beyond the usual efforts in such directions. The schematic explanations, which are plentifully supplied, are instructive in their simplicity, and give most substantial aid to the solution of many of the hitherto complex phenomena of allied and associated functions. Altogether the treatise is a model of its kind, and is destined to grow in favor by virtue of its numerous intrinsic merits.

The Earth in Relation to the Preservation and Destruction of Contagia. Being the Milroy Lectures delivered at the Royal College of Physicians in 1899, together with other papers on Sanitation by George Vivian Poore, M.D. (Lond.), F.R.C.P., Professor Principles and Practice of Medicine, University College, London. London and New York: Longmans, Green & Co., 1902.

To such as may have become acquainted with the author through his scholarly addresses and essays on the general subjects of rural sanitation in connection with disease prevention, it will be no surprise to learn that the present work is full of useful and interesting information, and contains a multitude of facts of the greatest value to the student of epidemiology. The earth, or humus, is proved to be a prime factor in the destruction of very many of the pathogenic microorganisms, and the study of disease prevention is, in the main, founded upon the consideration of such a probability. The relation of soil pollution, defective drainage, and contaminated water supply, infected milk and the like to epidemics of anthrax, tetanus, enteric and malarial fevers, dysentery, tuberculosis, and allied diseases is quite conclusively shown, giving the earnest reader much food for serious thought, and many useful and practical explanations for otherwise inexplicable phenomena. The book is full of interesting facts bearing on these points, and must necessarily appeal to every one interested in the study of the natural and commonsense views of disease propagation. His arguments appeal alike to the general practitioner of town or country, and his conclusions cannot fail to be of the highest practical value to all.

The Development of the Human Body. A Manual of Human Embryology. By J. Playfair McMurrich, A.M., Ph.D., Professor of Anatomy in the University of Michigan. With two hundred and seventy illustrations. Philadelphia: P. Blakiston's Son & Co, 1902.

The present volume occupies an intermediate position between the elementary works on embryology and the more elaborate books of Minot and the German writers. It presents, in a concise but intelligent form, the facts which are most useful to the student.

Part I, on general development, contains five chapters, which deal respectively with spermatogenesis, segmentation, the development of the external form of the embryo, the medullary germ, and the fetal membranes. The first two chapters are especially interesting, and present as clear an exposition of an intricate process as we remember reading.

Part II, organogeny, includes eleven chapters, each of which treats of the development of a different system or set of organs. Many of the details are necessarily dry and technical, but the author avoids foreign terminology as far as possible, and always succeeds in making himself intelligible. His style is pleasing, and his English good. A special feature of the book is the bibliography appended to each chapter, there being no foot-notes. The cuts, though not original, are numerous, and carefully selected, and are beautifully executed. A short concluding chapter in post-natal development will be studied with interest. The index shows careful work. A careful review of the book justifies the inference that the author has been exceptionally successful in preparing a manual on embryology which is readable, as well as of scientific value, adapted to advanced study, as well as to the class-room.

The Principles and Practice of Gynecology, for Students and Practitioners. By E. C. Dudley, A.M., M.D., Professor of Gynecology, Northwestern University Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago, etc. Third edition, revised and enlarged. With four hundred and seventy-four illustrations, of which sixty are in colors, and twenty-two full-page plates in colors and Monochrome. Philadelphia and New York: Lea Brothers & Co., 1902.

The success attained by this well-known work is shown by the early appearance of a new edition. The revision has been unusually thorough, and nearly one hundred pages of new matter have been added. The additions seem to be mainly in the paragraphs on surgical treatment, though we note that several sections have been rewritten. The diagnosis and differential diagnosis of various diseases have been arranged in parallel columns, as in the older works on gynecology. The subject of inflammation of the uterus and adnexa have been retouched, though we regret to see that the author still adheres to most of his former ideas on "chronic inflammation." His former tendency to devote a disproportionate amount of space to his own modifications in technic are still further accentuated in the present edition. The reader will not be able to withhold his admiration over the new plates (especially XVII to XIX, inclusive), which are certainly hard to beat. In its present form Dudley's Gynecology is fully abreast of the times, and the American profession may well feel a thrill of pride at this fresh evidence of "home talent." While we have never believed that the book was exactly suited for medical students, as a work of reference and a mirror of gynecological practice in this country it is not easy to find its equal. We need hardly add that as an example of book-making each new edition is, if possible, more attractive than its predecessors. Type, illustrations, index, and binding leave nothing upon which one could improve.

Diseases of the Skin. A Manual for Students and Practitioners. The Medical Epitome Series. By Alfred Schalek, M.D., Instructor of Dermatology, Genitourinary and Venereal Diseases, Rush Medical College (in affiliation with the University of Chicago), Chicago, Ill. Series edited by V. C. Pederson, A.M., M.D., recently Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, Columbia University in the City of New York; House Surgeon at the New York Hospital; Assistant Surgeon to the Out-Patient Department of the Roosevelt Hospital, and to the Vanderbilt Clinic; Physician-in-Charge, St. Chrysostom's Chapel Dispensary, New York City, etc. Illustrated with Thirty-four Engravings. Philadelphia and New York: Lea Brothers & Co., 1902.

The arrangement of the text of this little volume is

particularly convenient, especially for the student or the busy practitioner. The opening section treats of the anatomy of the skin, general symptomatology, general diagnosis, general internal therapeutics, and general rules in dermatology. Then follows a classification of diseases of the skin. The bulk of the text consists of an alphabetically-arranged description of diseases of the skin. There are thirty-four engravings. The general order of treatment of the subjects begins with the derivation of the name of the disease described, followed by the synonyms, definition, symptoms, course, etiology, pathology, and treatment. After the description of each disease is a group of questions, so that the book is very convenient for quizzing. There are numerous formulas throughout the book. As the author states, epitomes are not a substitute for the larger textbooks, though they are undoubtedly serviceable in laying a well-arranged foundation for later and more detailed work. The cardinal facts of dermatology, as accepted by the best authorities of to-day, are set forth in this volume, and it is an accurate, clear, and modern work.

Felix Hoppe-Seyler's Handbuch der Physiologisch- und Pathologisch-chemischen Analyse. Von H. Thierfelder. Seventh Edition Berlin: August Hirschwald, 1903.

The first edition of Hoppe-Seyler's Handbuch der Physiologisch- und Pathologisch-chemischen Analyse appeared in the year 1856 in the form of a small handbook of 300 pages. The present is the seventh edition. For two generations this book has remained the authoritative book of reference in physiological and pathological chemistry. The present volume has been com piled by Dr. H. Thierfelder, Professor of chemistry at the Physiological Institute in Berlin. The text has been brought abreast of the advance in research of the past ten years. Although his book must find its chief usefulness in the laboratory and to the physiological chemist, the physician will find it an authoritative reference to the chemistry of the body fluids occurring under normal and abnormal conditions. The book was not written for the physician, the subjects are treated of solely from the standpoint of the chemist, no place having been given to clinical or microscopic con siderations. The scope of the article upon the chemistry of the blood is still limited to the field occupied by that subject fifteen years ago, the newer physiological lines of research have not been treated. Neither has the article on the urine been brought abreast of the advances in clinical medicine. The recent work of Salkowski upon Penutosuria is referred to, but is not given in sufficient detail to meet the physician's practical demand.

The Elements of Bacteriological Technique. A Laboratory Guide for the Medical, Dental, and Technical Student. By J. W. H. Eyre, M.D., M.S., F.R.S. Edin. Bacteriologist to Guy's Hospital, London, and Lecturer on Bacteriology in the Medical and Dental Schools; formerly Lecturer on Bacteriology and Joint Lecturer on Practical Hygiene in the Charing Cross Hospital Medical School, and Bacteriologist to the Charing Cross Hospital, etc. With 170 Illustrations. Philadelphia and London: W. B. Saunders & Company, 1902.

As time advances and the great value of bacteriological research becomes more and more apparent, he who is familiar with this branch of medical science is more closely drawn to the conviction that, after all, bacteriology is essentially a science of technique, and that, for the advances which are yet to come, a greater perfection of technical methods is of the utmost importance. For this reason such volumes as the one here under discussion will be welcomed by all workers in this field. The foundations of the volume consist of notes which were distributed by the author to his laboratory classes, but the book as it exists is far more than a laboratory note-book, and comprises a minute description of the better laboratory methods which are in use to-day. From cover to cover the arrangement and treatment of the subject is most admirable, in that nothing is left to supposition, but every step is accurately considered in detail, so that he who consults it is left in no doubt as to "what to do next." The sections on the preparation and standardization of artificial culture media, and the methods of identification of bacteria deserve especial mention. In the former the author has met a great want in placing before the student such explicit instructions as are usually absent from bacteriological textbooks In the latter the subject is so-considered that, by following it, slip-shod and inaccurate work become an impossibility. It may safely be said that no work upon this subject has as yet appeared which can be compared with it in actual practical value to the bacteriological worker.

Treatise on Diseases of the Eye, Nose, Throat, and Ear. For students and Practitioners. By various authors. Edited by William Campbell Posey, M.D., Professor of Ophthalmology in the Philadelphia Polyclinic, and Jonathan Wright, M.D., Attending Laryngologist to Kings County (N. Y.) Hospital. Illustrated with 650 Engravings and thirty-five Plates in Colors and Monochrome. Philadelphia and New York: Lea Brothers & Company, 1903.

The era of "syndicate" books is now well established, and they are appearing in quick succession. Rarely, if ever, has a medical book appeared in a more attractive dress than the one before us. Bound in an attractive shade of green, with white lettering, printed in clear type and on good paper, it leaves nothing to be desired from the material point of view, and shows how high art may make at least the externals of medicine attractive.

An examination of the work shows it to be well worthy of its setting. Pages 1 to 685 are occupied by diseases of the eye, fifteen writers contributing as many chapters. Pages 689 to 1071 are devoted to diseases of the nose and throat, seven authors contributing. Pages 1075 to 1199 are given up to diseases of the ear, four authors contributing. An elaborate index, occupying thirty-eight pages, completes the book. Some surprise may be felt that in a work of such size the space devoted to the ear is relatively so small, but the chapters are eminently practical, and contain the essentials of otology.

In the space at our command it is impossible to specify the excellencies of the different chapters. Two characteristics running all through the volume may be mentioned: first, the entire absence of "padding," and second, a realizing sense on the part of the various contributors that they are physicians and surgeons first and special workers afterward. As a result, their contributions are well balanced. A strict censorship has evidently been exercized by the editors, whose standing in their respective specialties is too well known to call for comment here. We believe they have placed before the profession a model book, and one thoroughly up to date. New books of this kind are called for every few years, for these particular branches are rapidly developing along the lines of a clearer and more definite pathology, and the textbook of five years ago is, in many respects, hopelessly in arrears.

A Text Book of the Diseases of the Ear. By Prof. Adam Politzer of Vienna. Fourth Edition, revised and enlarged with 316 Original Illustrations. Translated at the personal request of the Author and Edited by Milton J. Ballin, M.D., and Clarence L. Heller, M.D. Philadelphia and New York: Lea Brothers & Co., 1903.

In the case of a treatise of this nature, and one written by an indisputed leader of his special field, the work of the reviewer must necessarily be confined to the mention of the changes over previous editions. This edition has been twice translated before, but the present translation has the advantage of having been submitted directly to the master himself, and bears, as its predecessors cannot have done, the personal impress of the distinguished Viennese clinician. As the preface truly says, "The free and masterly manner in which the author, in all his previous publications, discussed the various diseases of the ear, the thoroughness with which he treated aural surgery, the position which he holds among otologists and his numerous original investigations which form the basis of otology, are all sufficient guarantee for the excellence of any work bearing his name." The present work closes with an andex of the literature consulted in its preparation, and this is of itself almost a complete bibliography of otology, certainly of its vital parts. The use of different sizes of type enables one to save time in getting at the essential parts of the text as distinguished from those that are merely historical, statistical or descriptive. A careful reading of this treatise will bring to observation all that is vital in the otology of the opening of the twentieth century. Every topic has been brought up to date.

Luftreinheit, Aseptische und Atoxische Behandlung der Lungen zur Bekämpfung der Tuberkulose. Von Dr. med W. Zeuner, prakt. Arzt in Berlin. Berlin: August Hirschwald, 1903.

Here is another contribution to this ever interesting and most important subject. The writer first discusses anthracosis. He enumerates as the three causes of tuberculosis: Dust, also mechanical injuries, gaseous impurities of the air, and bacteria. He then speaks of the various occupations and the opportunities they offer for the development of the disease. Air-sepsis is then considered, the benefits of pure air, and the hygiene of the sleeping room.

Progress of Medical Science.

Journal of the American Medical Association, Dec. 27, 1902.

Three Cases of Involuntary Movements in Locomotor Ataxia.—The histories of the cases given in full by J. H. W. Rhein illustrate respectively choreiform movements, irregular slow contractions of groups of muscles, and a fine rhythmical tremor. Rhein believes that the text-books of the present day do not give proper attention to this class of symptoms. He does not believe that the cases described here were cases of disseminated sclerosis, as might be at first supposed, for the gradual progressive incoordinations, characteristic pains, bone changes, and ocular symptoms precluded in his own mind any doubt as to the correctness of the diagnosis. The patients might be described as being in the paralytic stage of disseminated sclerosis They did not present the mental changes, characteristic tremor, or nystagmus of disseminated sclerosis. In one case the lateral columns appeared to be involved, as indicated by the presence of the Babinski reflex; but such an involvement is not uncommon, as we not infrequently find post mortem that the ataxic affection has involved the lateral tracts.

A Peculiar Case of Recurrent Bullous Eruption.—The patient of W. S. Gottheil was a girl aged five and one-half years, of German parentage. Since her second year there had appeared each autumn a skin eruption of a peculiar nature. Each attack began with the appearance of a few watery blisters, which increased up to a certain size, and then either ruptured or dried up. From time to time new ones appeared, thus prolonging the course of the disease to several weeks or months. Then, quite spontaneously, the blisters ceased to form and the child was well. Subjective sensations were entirely absent, so that the child had had no treatment at all; and the sole reason that she was now brought to the clinic was the fact that the accident of location of some lesions in this attack does give her trouble. The first attack occurred in her second year; there were only two or three small bullæ on the backs of the hands, and the eruption lasted but a short time. The second attack in her third year was a little worse; there were more blisters, their size was larger, and the eruption lasted longer. In the attack of the fourth year the forearm and legs were affected, as well as the hands, and the severity of the symptoms was increased. The present (fourth) attack is the worst that she has ever had. It has been present since September (over three months); the blisters are larger than they have ever been; some have appeared on the mons veneris and abdomen, and there have been a number of lesions on the buttocks, thighs, legs, and arms. Each one takes two or three weeks to run its course, instead of a week, as did the early ones; and new efflorescences are continually coming out, so that since this attack began there have always been some score or two of lesions present in various stages at least. Within the last few days some large blisters had appeared on the ankles and soles; and the child had been unable to walk on account of the pain that they occasioned. There had been neither itching nor pain before or after the appearance of any of the lesions. Most of them were accidentally discovered when the child was being dressed or bathed. Gottheil believes that the diagnosis "benign pemphigus" best fits the condition, notwithstanding its periodicity, and the absence of an inflammatory areola around the bullæ.

Medical News, December 27, 1902.

Imitation, Suggestion, and Social Excitements.—John Bessner Huber declares that there are certain factors which may produce in the individual the same results as hypnotism does. These are mainly imitation, suggestion, and the force of inordinate social excitement. Under these influences he loses the power of calm observation, of logical thought; he becomes non-deliberative and impulsive. He has, for the time being at least, undergone reversion. He assimilates readily the ideas of others, however unreasonable they may be, and he proceeds in accord with those with whom he has associated himself. The varied manifestations of the disease called hysteria generally result from imitation and suggestion. It is well known that medical students are apt to consider themselves suffering from any disease which for the time takes up their attention. The writer describes certain revivals, and states that in them the same forces were at work—imitation, suggestion, and social excitement. The peculiar muscular movements of the participants were due either to congestion—that is, excessive determination of blood to the centers which control the muscular movements of the body, or to nervous explosions at the motor centers. Their form was determined by imitation and suggestion from the action of others. The individual had become a mere machine that could be worked upon. These aberrations of the motor centers were attended by, and themselves occasioned, an inhibition of the higher centers, so that reason, will, common sense, and decent self-control were paralyzed. For the time being, excessive, uncontrolled emotion had full sway. A crowd is an entity not at all analogous in its psychism to that of the individuals who compose it. It cannot be counted upon to arrive at conclusions by the same processes that are used by the self-poised individual. The crowd of the present day is much like that of the past. Great individuals exert marked influence upon their fellows. The universal tendency is, after all, toward improvement in all directions.

New York Medical Journal, December 27, 1902.

Rectrocæcal Abscess Developing Three Years after Removal of the Appendix.—The patient of T. S. Cullen was a frail lad of fourteen years. Three years previously he had had a severe fall followed by pain in the right iliac region, lasting several weeks. Shortly after this, and following exposure, acute appendicitis developed. On the tenth day the appendix was removed and the abscess drained. A week later there was a rise of temperature. Removal of some stitches evacuated a pint of pus. Recovery thereafter was without incident. One year before being seen by the author, the boy had a return of pain in the right iliac fossa following a blow. Ten days before being seen he had had a fall, and more pain at the site above mentioned, with evidences of deep induration just outside the scar of the former induration, and a moderate febrile reaction. The former scar was dissected out, and the convex lower end of the cæcum presented. The appendiceal stump was in perfect condition and free from adhesions, but the cæcum about 2 cm. above this was attached to the abdominal wall by a few adhesions, and a small portion of the omentum was also adherent at this point. On gently pulling back the omental adhesions between the cæcum and the lateral abdominal wall, a drop of pus made its appearance. The region was carefully walled off from the surrounding intestine and a pocket containing fully 100 c.c. of thick, creamy, grayish-yellow, most offensive pus evacuated. This cavity lay between the lower surface of the cæcum and the parietal peritoneum. The cavity was loosely packed with iodoform gauze and the intestines were walled off by surroundings strips. The temperature soon dropped to normal and the boy made an uneventful recovery, the wound closing completely in a little over four weeks. Cullen believes that at the time of the first operation there was a large abscess, and it is quite probable that a minute pocket of pus was left behind the cæcum. The tissues had been able to take care of the small purulent focus until the recent injury, as the abscess was between the peritoneum of the cæcum and that lining the abdominal wall.

American Medicine, December 27, 1902.

Ergot in Hemorrhage of Other than Uterine Origin.—Wm. B. Fenn concludes: (1) In profuse hemorrhage from the lungs, appearing in mouthfuls, the likelihood exists that an artery of considerable size is ruptured or eroded, and our object should be to quiet the circulation and lower the blood pressure. We should use rest and such drugs as aconite. Under such circumstances ergot should never be given. (2) In slow oozing the source of the bleeding is usually the congested capillaries in the mucous membrane. Ergot may stop the bleeding by constricting these capillaries; but as such hemorrhage is usually decidedly beneficial and stops when the congestion is relieved, and as ergot is not well borne by the stomach, and is decidedly disagreeable to take, the use is also here rather contra-indicated than otherwise. Digitalis, which also contracts the capillaries, would be quite as useful. It is said that Trudeau, at Saranac Lake, uses the drug for this purpose. (3) Uterine hemorrhage seems to furnish the pre-eminent, and perhaps the only, indication of ergot as an internal styptic.

A Case of Corrosive Sublimate Poisoning from a Vaginal Douche.—Horatio C. Wood, Jr., reports a case seen recently by him, which he thinks shows clearly that the vaginal mucous membrane, even without any gross lacerations, is capable of absorbing sufficient corrosive sublimate to cause toxic symptoms, and that the use of such douches, especially when carried out at home, is not free from danger. The case reported is that of a domestic of thirty years. Twelve days before coming to the writer she had applied at one of the city dispensaries for treatment for leucorrhœa. She was ordered a douche of corrosive sublimate, of 1 to 2,000, to be used daily. This caused much pain, which she was told was due to an improper syringe. With a new one she had the same result. She was advised to use half the former strength. Her urine had become the color of blood, after the first injection. After the third douche she had to take to her bed. The next day she was seen by the writer. She had a severe, heavy pain in the loins, frequent painful mic-

turition, loss of appetite, disgust for food, but no nausea or vomiting. The urine was smoky red, of acid reaction, and contained 0.35 per cent. albumin. Numerous red corpuscles were found, squamous and columnar epithelial cells, crystals of calcium oxalate, and tube-casts, chiefly of the hyaline variety, with an occasional blood-cast. The temperature was 99.4°, pulse, 108°. The face was puffy, with the peculiar waxy pallor of renal inflammation. Moderate doses of uva ursi were given, and diluents were freely used, so that by the next day the albumin had fallen to 0.15 per cent., and the patient felt much better. about two weeks from the time that the patient first presented herself to the writer, she felt quite recovered. Wood adds a warning against the indiscriminate use of corrosive sublimate as an internal antiseptic—a purpose for which it is in no wise fitted. Besides, it is very dangerous in the hands of the uneducated laity.

Philadelphia Medical Journal, December 27, 1902.

Influenza and the Nervous System.—Smith Ely Jelliffe asks if it may not be true that the action of the Canon-Pfeiffer bacillus is being seen more and more in its true colors and that, like the bacillus of diphtheria, it has a specific action on the nervous system, and that this is being recognized more clearly than ever before? As early as the fourteenth century its influence in causing psychoses was recognized. According to Kellogg, epidemic influenza or grippe, is productive of certain grave forms of insanity which are persistent and of uncertain outcome, especially in the aged. In making a diagnosis in influenza microscopical examination is imperative. This disease often leaves an impress on its victims for years after, in different forms of nervous and mental troubles, such as hypochondriasis, mania, and even general paralysis. It fatally complicates many other maladies. As to the statistics of suicide, the total increase between the rate during the years 1871-1875 and 1896-1900 was 66.6 per cent. in New York and 82.5 per cent. in Chicago. The increase between the first and the fourth interims (twenty years) was only 16.3 per cent. in New York and 29.3 per cent. in Chicago, but was nearly 50 (49.4) per cent. in New York and more than 41 (41.4) per cent. in Chicago in the ten influenza years, 1891-1900. The disease is highly contagious and one of the most virulent of the acute specific diseases. Every one is exposed more or less to the disease and should take every precaution to avoid it.

Sore Throat.—B. F. Randolph Clark states that not every patient who complains of sore throat is actually suffering from angina. This phrase is loosely used to describe any pain or discomfort about the mouth, fauces, or larynx. There are very many causes which give rise to discomfort in the throat. Sometimes rheumatism of the muscles of deglutition causes much pain, while on examination only a slight redness of the posterior wall of the pharynx can be seen. There may be paralysis of the throat muscles which will cause discomfort in the throat. Inquiry in such cases should be made as to recent diphtheria. Sore throat with a generally diffused redness of the pharynx is characteristic of simple catarrhal pharyngitis. It yields readily to glycerole of tannic acid, which should be applied after the surface has been cleansed with an alkaline spray. An initial dose of calomel and a gargle of chlorate of potash or rhus glabia are effective adjuvants. Hypertrophied tonsils may become inflamed and sore. Acute follicular tonsillitis is one of the most frequent causes of sore throat. The seat of the disease is in the crypts or follicles and each one must be cleansed out with hydrogen dioxide on cotton wound on a steel probe, and then wiped out with a strong solution of silver nitrate. The bowels should be opened and salicylates given internally. This treatment will always shorten, modify and often abort an attack. Phlegmonious tonsilitis or quinsy is most distressing. If seen before pus is fully formed scarification gives much relief. Hot liquids held in the mouth seem to give some relief and hasten the process. The bowels should be thoroughly opened. The writer mentions many other forms of sore throat, concluding with a few remarks on diphtheria. He declares that the early use of antitoxin, in some cases without waiting for the results of the bacteriological examination, is imperative.

Deutsche medicinische Wochenschrift, December 4, 1902.

Crossed Adductor Reflex in Syringomyelia and Neuritis.—L. Huismans reports two cases, one syringomyelia and the other neuritis, in which this rare sign was present. By striking the right patellar tendon there was produced, reflexly, an adduction of the left thigh while the right patellar reflex was absent. Westphal, who has observed this sign in neuritis, does not regard it as a true reflex, but as due to a nervous irritation, and it is possible that in cases of neuritis this view may be correct. The presence of the sign in syringomyelia, however, cannot be thus explained, on account of the chronic course of the disease, and in our present knowledge we must regard it as of genuine reflex origin.

Peculiar Origin of Syphilitic Gummata.—G. Kulisch thinks that mercury given by the hypodermic method is often not absorbed but remains for a long time in the tissues at the site of the injection. In this manner the tissues in such a location are damaged and reduced in resistency, so that they become especially predisposed to the formation of syphilitic gumma. A case is reported in which such a gumma developed in the left glutcal region. The history showed that five years previous hydrargyrum salicylicum had been injected hypodermically in that location. The gumma was opened and some of the broken-down muscular tissue chemically examined and found to contain mercury. It is probable that in such cases the mercury acts as a foreign body, causing a chronic inflammation, which predisposes the tissues to the action of the syphilitic poison.

Berliner klinische Wochenschrift, December 8, 1902.

Hæmolysins in Human Serum.—Mieczyslaw Halpern has studied the hæmolytic action of both normal and pathological human serum upon the erythrocytes of the rabbit. Taking 1 c.c. of a 5-per-cent. saline solution of such red blood cells as a standard quantity, he finds that if more than .07 c.c. of normal human serum is added a distinct hæmolysis always occurs. Occasionally smaller quantities of such a serum will produce hæmolysis, but such is not always the case. Further investigations show that with like quantities of blood the degree of the hæmolysis varies directly with the amount of serum added, and that with like quantities of serum the degree of hæmolysis varies directly with the number of erythrocytes used. In testing the hæmolytic power of pathological human serum against the erythrocytes of the rabbit it is found that in chronic non-infective conditions no appreciable variation from the normal occurs. The same holds true for the so-called blood diseases (anæmia, etc.) and all of the infective diseases except typhoid fever and septicæmia. In the former the hæmolytic power is greatly increased, while in the latter it is much diminished. Further observations may show that this sign may be of utility in the diagnosis of these diseases.

Antistreptococcus Serum in Scarlet Fever.—Adolf Baginsky reports comparative observations with the original serum of Aronson. Sixty-two cases were inoculated, of which seven died, a mortality of 11.3 per cent. Sixty-three cases, occurring in the same epidemic, were treated in the ordinary manner. Of these, nine died, a mortality of 14.3 per cent. A detailed study of the inoculated cases shows that in none was the course of the disease shortened or the symptoms favorably influenced; indeed, in most the course was lengthened and marked by the development of serious complications, such as nephritis, suppurative adenitis, and joint symptoms. In most of the cases 20 c.c. of the serum was given in one inoculation and not repeated. In a few, however, this dose was markedly increased, and in four six injections of 20 c.c. were given. Such an increase in the dosage did not in any way improve the results or lessen the complications. Recently Aronson produced a new serum which Baginsky has tried with somewhat better results, in that fewer complications have followed its use. It cannot be said, however, that it had any marked influence on the course of the disease, as ordinarily observed. These results are in striking contradiction to those recently reported by Moser and Paltauf. This may be due to the difference in the serum used by the latter observers, which was obtained from streptococci which had not been submitted to animal passage, as is the procedure followed by Aronson.

French and Italian Journals.

Aneurysm Treated by Injections of Gelatin.—Bordc describes a patient of forty-seven years who is not an alcoholic. He declares that he has never cared for wine. He takes an aperient once or oftener a week. He does not drink wine or alcohol in the morning, but milk or coffee. He is not syphilitic, and he denies ever having had the disease. His children show no signs of it. He is not rheumatic. His father died at the age of sixty-two years and his mother was fifty-seven years when she died. The patient states that his disease began with a continuous desire for sleep. He even slept sitting up. This phenomenon disappeared when he was bled. After this came crises of glairy vomiting. These occurred in the morning when the patient put his feet on the floor. They did not occur every morning. They were caused by coughing, and the milk and coffee were never expelled—only the glairy matter. These vomiting spells had lasted for several months

when the patient began to notice the symptoms for which he consulted Borde. For three months every morning, just as he stepped out of bed, never before, and never in the course of the day, he was seized with suprasternal pain, radiating toward his left breast, toward his ears, especially the right, and finally to the left arm and hand. After an hour or so of this pain it was terminated by an attack of glairy vomiting. The writer diagnosed the trouble as aneurysm of the left subclavicular artery, large as a small hen's egg, enlarged transversely, easily perceptible. The carotid and radial arteries throbbed violently. Auscultation discovered a double aortic soufflé. The thrill was perceptible on palpation. The patient was put on iodide of potassium and a milk diet. The injections of gelatin were given at night after the patient was in bed, and consisted of the following ingredients: White gelatin, 2 grams; Sydenham's laudanum, 5 drops; plain boiling water, 100 grams. The temperature was lukewarm, and a fountain syringe was used for the rectal injection. The injection was easily retained and absorbed. The patient has greatly improved under the treatment. Another patient with the same trouble was cured by the writer by this same method.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, November 30, 1902.

Intermittent Calculous Hydronephrosis.—M. J. Reboul reports a case of intermittent hydronephrosis from one calculus, which is interesting on account of the clearness of the symptoms presented by the patient before operation; on account of the variations of the volume of the kidney which increased in size at each crisis, and diminished during the interval; and the absence of pyelo-nephritis and the good results following nephrotomy and extraction of the calculus.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, November 30, 1902.

The Invulnerability of Epileptics.—Vitige Tirelli has found by experimentation that the blood serum of epileptics exercises a bactericidal power far superior to that of ordinary serum, and that especially it diminishes the development and the virulence of the staphylococcus pyogenes aureus. It is probable that this antipyogenous property is of influence in the production of that special condition of epileptics known as invulnerability. It is likely that epileptic serum possesses immunizing or curative properties in regard to the staphylococcus infection.—*La Riforma Medica*, November 29, 1902.

Heredito-Familial and Congenital Cardiopathy.—Gioacchino Arnone concludes from the case observed: (1) That the mitral apparatus may be deformed at birth; whence cases of pure stenosis. (2) If the mitral apparatus becomes affected following some slight cause, this is due in the majority of cases to the fact that owing to prenatal malformation it is a *locus minoris resistentiæ*. (3) Congenital malformations are more frequent on the left than on the right side of the heart. (4) It is the physician's duty, as far as possible, to correct the hereditary taint, and from the point of view of prophylaxis to prevent the marriage of persons with marked hereditary cardiac affection.—*La Riforma Medica*, November 20, 1902.

Essential Anasarca.—Paolo Bacialli reports the case of a woman who became affected with anasarca after falling into cold water. There was hypophonesis of the respiratory apparatus without indication of any inflammatory process, and a slight increase in the size of the liver and of the spleen. The author holds that there was no possibility of bacterial toxæmia in the case, but that the sudden chilling and fright acted as a stimulus to the central and peripheral nervous system, inducing a double action—one on the small blood vessels, causing hyperæmia and serous infiltration, and the other on the renal circulation, diminishing and almost suppressing the secretion of water and salts.—*La Riforma Medica*, November 28, 1902.

Peribiliary Peritonitis, with Frequent Crises of Hepatic Colic; Laparotomy; Rupture of Adhesions. Recovery.—M. J. Braquehaye of Lunis has had a patient who at one time had crises of hepatic colic with passage of gallstones in the stools. A dozen years later she was attacked by sudden and frequent hepatic paroxysms, with jaundice by retention, swelling and pain in the cystic region. Laparotomy was performed, followed by careful exploration of the bile passages. It was discovered that there were no calculi, but pericystic inflammatory adhesions with all the neighboring organs. These adhesions were ruptured without opening the bile passages. The patient recovered after an attack of malaria, excited by the operation.—*Revue de Chirurgie*, November 10, 1902.

A Contribution to the Study of Cyclic Vomiting in Children.—F. Valagussa concludes, from the cases observed, that recurrent vomiting occurs in children who have inherited the uric diathesis. The disease forms a part of the pathology of metabolism, and should be considered as absolutely distinct from diseases of the gastrointestinal tract. The vomiting occurs at irregular intervals, and is decidedly influenced in both duration and severity by treatment. The disease is not a morbid entity, but a complex syndrome of which the vomiting is the chief symptom. The pathogenesis of the recurrent attacks is in relation with an acid intoxication of the organism caused by poisons as yet unknown, upon uric-acid patients. The syndrome of recurrent vomiting is to be considered as an equivalent of gouty attacks in children with hereditary arthritis.—*Il Policlinico*, November, 1902.

The Effect of Cocaine on Intestinal Absorption.—Alfredo Baldacci and Guido Guidi, from the result of their experimentation, conclude that the application of a solution of cocaine to the intestinal mucosa retards the process of absorption, but does not entirely suppress it. It remains to be seen whether larger doses will entirely prevent absorption. It is worthy of notice that fatty substances are affected in about the same degree as soluble ones. This might possibly be due to a partial saponification of the fats in the intestines from the action of small amounts of bile contained therein, or from their emulsification by the enteric juices. In any case the point has been proved that both fats and soluble substances are usually absorbed by the intestines, not by a purely physical process, but by one which includes the activity of the intestinal epithelium.—*La Riforma Medica*, December 2, 1902.

The Action of Alternate Freezing and Thawing on the Vitality and Virulence of Some Pathogenic Bacteria.—Francesco Testi, by subjecting various forms of microorganisms to the repeated and alternate effects of freezing and thawing, found a marked diminution of mobility in the typhoid bacillus, and the cholera vibrio; in stained preparations a transformation of the latter into rounded coccus-like forms. There was a rather marked plasmolytic condition of the bacilli of typhoid, glanders, and diphtheria. There was no morphological modification in the bacteria of chicken cholera. After alternating cold and thawing twelve times, all the germs (excepting those of chicken cholera on two occasions) were developed in cultures. The injections of these germs cultivated after the experimentation was in every case fatal to the animal inoculated, with the exception again of the germs of chicken cholera, which in three cases failed to occasion any pathological disturbance.—*La Riforma Medica*, November 19, 1902.

Abdominal Hysterectomy for Fibromata.—Lafourcade has performed seventy-two abdominal hysterectomies for fibromata in the last four years: ten total, with six recoveries, and sixty-six supravaginal with sixty-two recoveries and four deaths, two of which were due directly to the operation. These mishaps occurred in the first thirty operations, and he has performed forty-two successive abdominal hysterectomies without a single failure. The operative prognosis is the same in complicated cases as in simple cases, on the condition that certain fundamental rules are observed. He has encountered a number of cases in which there were both a fibroma and acystic tumor of the ovary, or of the broad ligament, with lesions of the adnexa, or an epitheliomatous uterus. The post-operative, vicarious troubles are very much relieved by the application of leeches, or by the administration of ovarine in tablets or powder.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, November 23, 1902.

Drainage of the Pericardium and of the Pleura.—Terrier and Reymond, among other sections on the surgery of the heart and pericardium, discuss this subject. Drainage is indicated when there is danger of abundant effusion or of infection. But when this fear is past, then drainage should be discontinued. In cases of pneumothorax it has been thought prudent to drain the pleura. But it is now known that traumatic pneumothorax, or, in other words, aseptic, can be closed without any inconvenience. On the other hand, pneumothorax that is drained persists for that very reason, and the pleura only awaits an occasion for infection. It contaminates in its turn the pericardium when that should have been closed. Among conditions tending to facilitate contamination are the persistence of the pleural cul-de-sac in front of the pericardium and suture of the pericardium, each stitch of which involves the mediastinal layer of the pleura.—*Revue Française de Médecine et de Chirurgie*, November 24, 1902.

An Unheeded Peril in Preserved Meats.—Giovanni Grixoni has found that the fluidification of the gelatin contained in cans of meat, and in bottles of concentrated broth is a very certain sign of damage, even when other signs are lacking. This fluidification is due to the action of living bacteria and trypsinic ferments secreted by them. Peptonized preserved meats have toxic powers, for, whether inoculated into, or eaten by rats and mice, they cause their death. The toxins produced in fluidified preserved meats have a powerful antibacterial action, prevent the development of putrefaction, and are soluble

in water. They are destroyed by a temperature of 100° C. Serum diagnosis in infections of alimentary origin is an excellent method for the recognition of the etiological agent. The prolonged presence of microbes in the can profoundly modifies their biological properties, prevents their development, and finally causes their death. Cans containing living germs, even if these are saprophytic, should be excluded from the dietary.—*La Riforma Medica*, December 3, 1902.

Total Extirpation of the Bladder and of All the Genital Organs for a Papillomatous Tumor of the Bladder.—M. A. Hogge treated this patient, a man of forty-five years. His trouble dated back to 1895 or 1896. In the latter year, Hogge made a hypogastric incision followed by as complete ablation as possible of a voluminous papilloma, largely implicating the region of the trigonum. Recurrence took place and in 1898 another operation was performed: Perineal incision, detachment of the bulb, prostate, seminal vesicles on one hand, of the rectum, of the anal sphincter on the other; symphysrotomy, separation of the pubis, detachment of the perivesical peritoneum, and the seminal vesicles; ligature of the lower ends of the uretus, the removal in a mass of the bladder, prostate, vesicles, and external genitals; suture of the pubis with silver, and cutaneous suture of the abdominal wall. The results were satisfactory. Three years later the patient is in a very fair condition. The kidneys are only moderately diseased, and the urine instead of flowing into the rectum, flows out of a perineal fistula, the transplantation of the uretus in the rectum not being maintained.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, November 30, 1902.

The Transmission of Typhoid Fever by Oysters at Constantinople.—According to Remlinger, the transmission of typhoid fever by oysters is far from rare at Constantinople. The city is surrounded on all sides by water. This water which receives the sewage of a population of nearly two millions of inhabitants is extremely rich in organic matter. It consists of a mixture of sea water, fresh water, and sewer water. This is considered ideal for the rapid growth of the oyster. The bacteriological analysis of the oysters which are developed under these conditions shows a large number of microorganisms and discloses numerous harmful species. It is often noted that patients are seized with diarrhœa a few hours after eating the contaminated oysters. This diarrhœa lasts from eight to twelve days, after which the symptoms of typhoid fever develop. It would be interesting to know if Eberth's bacillus is ingested at the same time with the putrid bacilli, which cause the diarrhœa; or if these latter act by increasing the virulence of the typhoid bacillus. At other times, two persons eat of oysters from the same lot, and one develops diarrhœa and the other typhoid fever. In the first case it seems that the diarrhœa in expelling the typhoid bacilli soon after their ingestion plays a happy rôle.—*Le Bulletin Médical*, December 3, 1902.

Spontaneous Luxations in the Course of the Principal Infections.—A. J. L. Étienne calls attention to certain dislocations which take place in illness or convalescence. Various names have been used to indicate them. These secondary dislocations are consecutive to certain maladies, such as typhoid fever, acute articular rheumatism, scarlatina, variola, gonorrhœa, and streptococcic infection. They possess anatomical and clinical signs which are perfectly distinct and which make of them a morbid entity. There have been various theories advanced as to their cause: One is the accumulation of liquid in the joint; another, vicious attitude of the extremities acting on articulations already diseased; still another is based on the atrophy, the paresis and paralysis of certain muscles joined with the contraction of opposed muscles. It is in the hip that the sudden dislocations are the most frequent. Sex does not seem to be a factor of great importance. It is in the great majority of cases an affection of infancy or adolescence. Nevertheless, it has occurred at the age of thirty or forty years. All of the pathological dislocations have the common characteristic of being consecutive to an articular affection. They are generally incomplete and dependent upon the position of the extremities, which is itself dependent upon muscular action. These dislocations are very easy to reduce in the beginning. Later they become very difficult and often impossible to reduce.—*Revue Française de Médecine et de Chirurgie*, December 1, 1902.

Actinomycosic Appendicitis.—Léon Thévenot reports the case of a young man of eighteen years, who was first a farmer and later a groom. He had an attack of appendicitis. The existence of an intra-peritoneal mass of wooden hardness suggested that the lesion might be due to actinomycosis. Examination confirmed the suspicion. It was discovered that he had for a long time been accustomed to carry in his mouth and to nibble blades of grass, and grains of oats or of wheat not yet ripe. The teeth were fairly good. But in the last three years he had lost three or four molars. There was also a little tartar. The attack began suddenly without apparent cause, without previous gastric troubles, without any prodrome. He experienced violent and continuous pain in the right iliac fossa, and he had to take to his bed. He was made to rest, and observe a careful diet. Laudanum compresses were put on the abdominal region. He improved, and an operation was advised. On admission to the hospital he did not complain of pain, but of great lassitude, persistent anorexia, and slight constipation. His general condition was good. On opening the abdomen, the appendix was resected. It was apparently inflamed and slightly swollen. A drain of iodoform gauze was inserted. Seven days latar the patient complained of diffuse pain in the right iliec fossa and along the antero-internal surface of the thigh. But these symptoms soon disappeared. The wound cicatrized *very* slowly, and in contact with the appendicular stump there was a very hard mass which appeared to increase. Examination of scrapings revealed the ray-fungus which examination of the intra-appendicular liquid had failed to discover. The patient was submitted to the iodine treatment. The wound soon changed and cicatrized. There was only a hard nodule left, which became completely resolved in a few weeks. Several months later the patient wrote that he was completely cured.—*Gazette des Hôpitaux Civils et Militaires*, November 18, 1902.

The Edinburgh Medical Journal, December, 1902.

Cataphoresis in the Treatment of Gout, Rheumatism, and Rheumatoid Arthritis.—Charles Begg gives the method of using this procedure to obtain the best results. He says that in gout it is clearly asking too much to expect it to dissolve and remove extensive and old chalky deposits; but any deposit, however slight, forms a nucleus for the precipitation of fresh insoluble material, and, although this may be continually going on to a slight extent, it must be copiously and rapidly precipitated with each fresh attack of inflammation; and this is the time when we can do good, both by soothing the pain and by the action of the positive electricity checking the inflammatory process, while all the time it is driving a stream of potassium bicarbonate into the tissues of the joint. In rheumatoid arthritis the method does great good in the earlier stages, both in reducing the swelling and soothing the pain. In rheumatic arthritis, in addition to the soothing and massage effects, there is a probability of the alkali also being useful, and the method can help us at any stage of the disease.

The Large Intestine Regarded as a Syphon.—R. W. Leftwich has, from his reasoning in regard to the anatomy of the colon and from the results of his experimentation, reached the conclusion that the large intestine does not act on its contents by peristalsis but by syphonage. This explains the customary single evacuation per diem. With a continuous flow and no sphincter above the rectum, one would expect frequent evacuation, and this is the case in such quadrupeds as maintain the horizontal position of the trunk at all times, and have, in consequence, no syphonage. The author suggests that the force used to move the column of feces and start the flush is hydraulic. We have a small cylinder, the ileum; a large cylinder, the cæco-colon; and a piston, the column of feces, inseparable, albeit, from the body to be moved. The difference in the sectional areas will represent a multiplication of the power by six. Definite functions have now been assigned to the rectal pouch, the sigmoid flexure, the great arch of the colon, the cæcum (two), and the intestinal gas. A feasible explanation has also been tendered for the great discrepancy in size between the large and small intestines.

The Treatment of Cancer by Phototherapy.—Dawson Turner says that external cancer, before ulceration, may be treated either by the Finsen light or by the *x*-rays, and, as a rule, he prefers the Finsen light. After ulceration the Röntgen rays should be used. For internal cancer the Röntgen rays only can be used. The clinical results of the treatment are: (1) To remove or diminish the pain; (2) to loosen adhesions and to cause the disappearance of the contracting and tightening feeling; (3) to cause an ulcerating and sloughing surface to take on a healthy and healing aspect, and to diminish in size through the growth of epithelium from the edges; (4) to dissipate and remove cancerous and sarcomatous tumors. The author reports eighteen cases, nearly all inoperable, and therefore the more difficult to treat successfully, and yet all but three of them showed improvement, and some of them remarkable improvement. The breast cases are the most successful, and the tongue the least. Recurrence is usual, and in no case has the author seen a definite cure; the treatment seems to be a race with the disease, but the recurrences yield as before, and a stage is arrived at in which one or two short exposures per week will suffice to keep the disease in abeyance and to remove any distressing symptoms.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 11, 1902.

R. G. FREEMAN, M.D., CHAIRMAN.

Case of Foreign Body in the Intestine.—Dr. L. EMMETT HOLT reported this case. The patient was a child of six months, the son of a physician. He was in the habit of swallowing foreign bodies. Early in June he had an attack of measles, and after the temperature had fallen as usual, it rose again, and he developed an acute mastoiditis. The ears were punctured, but the temperature remained between normal and 106° F. for several weeks. The child recovered without a diagnosis having been made. The temperature would remain normal until noon or 3 P.M., and then would rise rapidly almost to 106°. The father made innumerable blood examinations, but malaria was excluded. The lungs were absolutely normal throughout the attack. In the third week of the attack the child was found one morning cyanosed and struggling. It had been playing with a paper of safety-pins a few minutes before. The trained nurse entered the room at this time and removed a handful of the pins from the mouth, but it was certain at the time that at least one pin had been swallowed. This was on July 5, and on July 10 the mother reported that three safety-pins had been discharged from the rectum, including one which was bent like a fish-hook. The child then had a large constipated movement, and although the trained nurse insisted that it was free from pins, the mother examined the stool very carefully, and was rewarded for her trouble by finding four more safety-pins. Dr. Holt also referred to the case of a child who had been playing with a set of toys, and as a result, had swallowed a sugar tongs, about one inch and a half long, and a knife, which was a little longer. This emphasized the necessity for great care in selecting for little children toys having parts which cannot be loosened and swallowed. The speaker said that he had made an autopsy on a child some years ago, and had found a safety-pin impacted in the larynx. It had apparently caused death.

Acute Pyogenic Infection in the New-born.—Dr. HOLT reported this case. He said that on October 13 a child had been returned to the New York Foundling Hospital because of sickness. The baby had been apparently well until fourteen days old, when a few dark spots were noticed on the extremities. These increased very rapidly, and on the third day the lower half of the face, the neck, the entire skin of the extremities and the buttocks were covered with a hemorrhagic eruption. The majority of the spots were one-fourth of an inch in diameter, and were irregular in shape; those on the buttocks were very close together. Surrounding each hemorrhagic area were slight redness and marked induration. There was slight bleeding from the umbilicus. On the gum nothing was visible except in the site of the upper incisor tooth, where there was a hemorrhagic area about half an inch long. There was no scaling of the palms and no hemorrhages into the eye. The examination of the internal organs was negative, with the exception of a decided enlargement of the spleen. The child's temperature was 100.8° F. in the rectum. During the next thirty-six hours the child failed rapidly, and it died two days after admission, without new symptoms, except that the urine was slightly blood-stained and râles were present over the lower half of the lung. At the autopsy the left lung was found to be the seat of some atalectasis and purulent meningitis, with abundant exudate on the convexity and at the base of the brain. The ventricles were distended with serum containing flocculi of pus. Cultures were made by Dr. Wollstein from the skin during life, and from the internal organs after death. A pure growth of the staphylococcus pyogenes aureus from the spots on the skin, from the blood of the hypogastric artery, from the blood of the heart and liver, and from the pus in the brain.

The speaker said that although the pyogenic infection of the newly born was very simple in its etiology, it was very complex in its symptomatology. Apparently this child was quite well up to the fourteenth day of life, and the hemorrhagic eruption appeared from the fourteenth to the eighteenth day. This was the most abundant eruption of the kind that he had seen. It was also interesting to note that although the only lesion of importance was a meningitis, the child presented no symptoms of this disorder. The temperature never rose above 101° F., and there were no convulsions. Of course, the infection clearly entered through the umbilicus, and as a result the rule had been made in the Foundling Hospital that no infant should be sent out from there until the umbilicus had healed. It was worthy of note that this child presented no peritonitis, and this had been his experience in other similar cases. In connection with this, mention was made of a child seen recently at the Lying-in Hospital. It had been brought back by the mother nearly four weeks after its birth with the assertion that its thigh had been broken at the hospital, but the subsequent developments, particularly the symmetrical development of lesions, proved that the case was one of infection.

Dr. H. L. K. SHAW of Albany said that he had seen last winter, with Dr. Hun of Albany, a babe of ten months in whom the temperature remained between 103° and 105° without obvious cause. The blood examinations showed no leucocytosis. On the twelfth day the temperature fell somewhat, and on the fifteenth day a long bristle was passed per rectum.

Dr. J. FINLEY BELL of Englewood said that the rule was to give a dry and bulky diet to children who had swallowed foreign bodies, and hence it seemed to him very unwise to liquefy the fæces by giving an enema, as had been done in one of the cases reported.

Dr. HOLT said that he had learned of the case of a child who had suffered from a severe attack of intestinal disorder for the greater part of the summer. Improvement began at once upon the passage of a large ball of hair. The child had been accustomed to sit upon a large bear's skin rug, and had evidently swallowed, little by little, a considerable quantity of the hair. After the passage of this foreign body recovery was complete. It seemed to him imprudent to give little children toys covered with hair or wool.

Report of a Case of Adenoids with Malaria.—Dr. W. F. CHAPPELL reported the following case: A girl of one month developed symptoms of nasal obstruction, and although when four and a half months old she weighed 16½ pounds, she was very pale. When five months old he had removed ten small pieces of lymphoid tissue from the nasopharynx without anæsthesia. On the following day the child was very bright, and at once began to gain rapidly in weight. A few weeks later she became irritable and restless, and then the temperature rose rapidly. On examination a slight enlargement of the spleen led him to suspect malaria. It was then ascertained that the child had been carefully protected through the summer from mosquitos, but during a birthday party the mosquito netting had been unintentionally left off, and the child had received two severe bites from a mosquito. These were so severe that they remained for two weeks. Examination of the blood showed the presence of the organisms of tertian malaria. It was found necessary to push the quinine, so that the little one took altogether a total of 241 grains in twenty-seven days. The quinine was stopped on November 6, and since then there had been no return of the malaria. The first malarial symptoms had appeared ten days after the child was bitten. He had subsequently obtained thirty specimens of mosquitos from the locality

in which the child had become infected, and of this number three were anopheles.

Officers Elected.—Dr. Henry Heiman was elected Chairman, and Dr. L. E. LaFetra, Secretary of the Section.

SECTION ON GENERAL MEDICINE.

Stated Meeting, Held December 16, 1902.

James K. Crook, M.D., Chairman.

A Brief Review of Some of the Etiological Factors in Intestinal Dyspepsia.—Dr. E. Franklin Smith read this paper, and said that intestinal dyspepsia might be due to abnormalities of secretion, of absorption, or of peristalsis. After a brief review of the predisposing factors, he followed Hemmeter's classification, dividing his subject under the following nine headings: I. Intestinal Dyspepsia, Due to Anatomico-Pathological Alterations of the Intestinal Walls, Nerves, Lymphatics, or Blood Vessels. Diseases or injuries of the small intestines might be accompanied by dyspepsia if the lesion deprived the mucous lining of its power of absorption and, under this heading, there were included inflammatory lesions, neoplasms, obstructions, deformities, and displacements, such as enteroptosis, or splanchnoptosis. II. Absence, or Deficiency of the Intestinal Digestive Secretions, Especially of Bile and Pancreatic Juice. (1) The Succus Entericus. So little was known with regard to the intestinal juice that no satisfactory explanation as to how abnormalities of this secretion affected digestion had thus far been given. (2) The Bile. Just what part the bile played in the digestive process had always been open to much discussion, some claiming that it took a very important and essential part, while others claimed that it was simply an excretion. (*a*) Acholia. A lessened production of bile might occur from causes which diminished the size of the liver, from hunger, febrile diseases, and uræmia. Certain chemical agents might reduce its secretion. A lessened amount of bile reached the intestines when there were any obstructions by gallstones, cholelithiasis, catarrhal icterus or neoplasms which pressed upon the common gall-duct. As a result of a lack of the normal amount of bile, it lost its antiseptic and purgative action, and there followed an increased fermentation with the development of irritating products giving rise to intestinal dyspepsia. (3) The Pancreatic Juice. Under this heading he considered (*a*) Succorrhœa pancreatica. A reflex pancreatic secretion might be increased by any irritation of the lingual nerve, or the central end of the vagus. (*b*) Hypochylia and achylia pancreatica. A diminution, or absence, of the pancreatic juice might be due to atrophy of the gland structure, either partial or general; it may be due to nervous influences; it might occur in anæmic conditions, in subnutrition, or from certain chemicals; it might result in febrile disturbances, or in carcinomatous or other malignant diseases of the pancreas. Chewing and smoking tobacco were causes of deficiency or altered pancreatic secretion. III. Intestinal Indigestion Due to Qualitative or Quantitative Irregularities of Diet. Under this head he made three subtypes: (1) The diet might be excessive in quantity, and could not be transformed in a normal manner by the amount of digestive secretions present. (2) Although normal in amount, it might be irregularly and unhealthfully mixed. There might be an excess of proteids, of fats, or of carbohydrates. Over-eating was a very frequent cause of intestinal dyspepsia, if the food was not completely digested, as this permitted an increase of germs. (3) Abnormal and injurious substances might be contained in the diet, in the form either of toxins, the result of putrefaction and fermentation in the food itself, or of chemical substances, added by accident or by design for therapeutic reasons. Many chemicals and medicines taken for the relief of gastrointestinal diseases often exerted a deleterious effect upon the normal course of digestion. The imprudent use of drugs, especially laxatives, might cause intestinal dyspepsia. Many drugs given to relieve supposed indigestion and dyspepsia were really the causes of them. A review was given of the drugs, condiments, articles of food, and toxins, which were capable of giving intestinal dyspepsia. IV. Intestinal Dyspepsia Due to Abnormal Bacterial Activity. Bacteria were not essential to good digestion and health, although he stated that there were a very large number of bacteria which, through their fermentative action, could convert starches into sugars and also cause these sugars to ferment. Among the more common protozoa found in the intestines was the amœba coli, which appeared to exert a necrotic and solvent action upon the tissues, causing a remarkable destruction with the formation of nuclear fragmentation and detritus, the lesions being particularly found in the submucous coat of the large intestines. The superficial epithelium of the intestine was the chief protective agent against the invasion of bacteria; when the epithelium was well preserved bacteria were not found in the submucosa; whereas, they might be seen entering at places where the epithelium had been injured or destroyed. As many as fifty known species of microorganisms had been identified at various times in the fæces of those suffering from intestinal dyspepsia. V. Intestinal Dyspepsia Due to Abnormal Gastric Chemistry. The fact was well known that abnormalities of the gastric secretions might produce intestinal dyspepsia, because of the meteorism and disturbances in peristalsis which followed upon hyperchlorhydria, and the diarrhœas noted in achylia gastrica. The entrance of chyme into the duodenum caused a reflex secretion of the pancreatic and biliary fluids to a sufficient extent to neutralize the acid contents of the stomach and establish a degree of alkalinity which was most suitable for the action of those ferments which completed the processes of digestion. An abnormal acid state of the chyme might completely neutralize the alkaline secretions of the small intestines and so stop the digestive process. A very prolific element in the cause of intestinal dyspepsia is deficient mastication and insalivation of the food. He believed that sooner or later every case of aberration of function of one portion of the intestinal tract would be followed by some derangement of other portions. VI. Intestinal Dyspepsia of Nervous Origin—Neurasthenia Intestinalis. This demanded notice on account of the one prominent symptom of intestinal dyspepsia, although, logically, it belonged among the neuroses. In all works upon practice of medicine, the prominent influence of the nervous system upon the secretion of the digestive fluids had been emphasized, and he did not consider it surprising, therefore, that there should exist a state of intestinal dyspepsia of purely nervous origin which could not be classed under any other heading. VII. Intestinal Dyspepsia Caused by Abnormal Substances, or Irritation, Reaching the Intestines from the Blood. Here were classified the dyspepsias occurring in uræmia, malaria, septicæmia, croupous pneumonia, gout, and many other diseases, including the infectious diseases. VIII. Intestinal Dyspepsia Due to the Activity of the Intestinal Parasites (exclusive of Bacteria), Worms. All varieties of intestinal worms might give rise to intestinal dyspepsia, whose severity depended upon the closer approach to, or departure from, the health of the individual. IX. Intestinal Dyspepsia Due to Hyperperistalsis or Excessive Motility of the Bowel. Under this heading he considered three conditions, as follows: (1) Motor Neurosis. (*a*) Nervous, or morning diarrhœa was a condition observed in nervous and hysterical women and hypochondriacal men. The motor nerves became abnormally irritated from emotional disturbances which excited the diarrhœa. (*b*) Nervous constipation was a condition in which there was a nervous inhibition of peristalsis, occurring in the hysterical and emotional as the result of worry, fright, etc. (*c*) Enterospasm, or nervous cramps, was another condition in which

was found an annular constriction of one portion of the intestines from some peculiar reflex; as a result, the contents of the bowel were forced against the narrowed portion, distending the intestines above, causing colicky pains. (2) Sensory Neurosis. (*a*) Enteralgia, colic, or enterospasm was another condition frequently met with in the hysterical, neurasthenic, and anæmic subjects. Coarse, indigestible, or decomposing food migh be a cause as well as scybala, gallstones, enteroliths, or other foreign bodies. Local irritation from disease of other organs, such as the uterus, ovaries, kidneys, or bladder, might be a causative factor. Taking cold was a common cause of colic in some. (*b*) Proctospasm, or neuralgia of the rectum, was quite common in the neurasthenic patient, and was often secondary to rectal irritations, as fissure or fistula. (*c*) Anæsthesia. This was a condition in which there was a loss of sensitiveness of the intestines to the stimulus of food, which ordinarily caused peristalsis. It was quite common in organic brain diseases. (3) Secretory Neurosis. In this no inflammatory lesions were found, and it was supposed to be a functional disorder, or a secretory neurosis of the mucous follicles of the colon causing the secretion of a mucoid substance.

Intestinal Indigestion and Its Relation to Arterial Sclerosis and Renal Disease.—Dr. Leonard Weber related, from a large number of observations, three cases of chronic gastrointestinal indigestion in the course of which interstitial nephritis developed, of which the men finally died. He considered these cases of chronic disorder of the gastrointestinal tract as furnishing the existing cause for arterial and renal sclerosis of great clinical value, in so far as he had attended upon them for twenty-five or thirty years, watching them almost from beginning to end, and was in a position to exclude all other factors in the etiology of the chronic nephritis. In calling attention to the fact that physicians who see much of infantile diseases have lately become aware that cholera infantum and similar acute and subacute gastrointestinal dyspepsias and catarrhs are not infrequently complicated, and even terminated by, acute nephritis, he remembered that Dr. A. Seibert of this city had related such cases to the New York Academy of Medicine four or five years ago If ptomains and other toxins can do this in acute cases why should not similar poisons chronically supplied insidiously produce arteriocapillary and renal changes of the slowly progressive variety of interstitial inflammation? Dr. A. E. Elliot of Chicago, at the last meeting of the American Medical Association, declared his belief that absorption of toxic material from the gastrointestinal tract played the most important part in the etiology of chronic nephritis. He pointed out that when the kidneys failed in their excretory function, because of the toxic substances which were present in the blood, the liver then failed to metabolize substances which came to it, and added its own quota of toxic material to the blood, thus still further irritating the kidney, and that the vicious circle thus formed continually deteriorated the general condition of the patient. Dr. Elliott's contentions were favorably received by many here and abroad, and there certainly was this great point to make one cling to his belief, that, if true, it threw a far more hopeful light upon the treatment of this disease, if seen at an early stage, than seemed to be shown by other views with reference to its etiology. In a paper published in the *Post-Graduate Journal*, October, 1898, the author tried to prove that interstitial inflammatory processes of the kidneys were brought about through the toxins of tissue-metabolism acting upon the parenchyma of the urinary organs while coursing through the lymph spaces of the renal cortical substance, and related a number of already established cases of renal and arterial sclerosis, which had been greatly benefited by the persistent use of small doses of the iodides, *i.e.* four to five grains three times a day; he thought that the potassium iodide inhibited the proliferation of connective tissue, induced disintegration and fatty degeneration of corpuscular material, and the removal of the same by stimulating the vasomotor nerves and increasing the functional activity of the parts. It was self-evident that, in order to prevent kidney disease arising from the toxins from gastrointestinal indigestion, we must resort to intestinal antisepsis by more or less frequent doses of calomel, lavage of the colon, proper diet, regulation of the patient's mode of life, etc. Further he was convinced that through faulty metabolism in the tissue cells many active poisons—toxalbumins—were produced which were at least as powerful in producing organic disease as the intestinal toxins, if not more so. It was, in fact, the interstitial, intermediate toxins which were the originators of genuine autointoxication. To this group of systemic autotoxins belonged the constitutional diseases, such as gout, uric-acid diathesis, diabetes, and its acute exacerbations—diabetic coma, uræmia, and eclampsia. Also the diseases caused by the anomalous function or loss of function of certain organs: Graves' disease, myxœdema, cretinism, Addison's disease, and pancreatic diabetes. For the purpose of early diagnosis of these conditions, blood examinations would be of greater service than those of the urine, for the blood was the chief carrier of the toxalbumins, and we must hope to recognize their presence and effects by the study of the changes in the composition of the blood. The doctrine of autointoxication was already firmly established by thousands of good clinical observations, and it must be conceded that the intestinal and interstitial toxins irritated the kidneys, producing albuminuria, desquamation of epithelia, and nephritis in passing through them.

The Treatment of Intestinal Indigestion, with Preliminary Remarks on the Diagnosis.—Dr. John C. Hemmeter of Baltimore read this paper, which was a critical summing up of that which was of clinical significance and practical importance concerning dystrypsia; this he presented, as it was conceived through personal critical experience. In acute enteritis of the jejunum and ileum the most objective evidences were found in abnormal conditions of the stools, mostly diarrhœal and thick, like gruel; the characteristic features were (1) shreds of mucus intimately mixed with the fecal matter; (2) bile pigments; (3) epithelia and muscle fibers stained with bile. The exact localization of catarrh of the small intestines was practically impossible.

Dyspeptic Diarrhœa in Connection with Stomach Diseases.—In achylia gastrica severe diarrhœas were encountered during which the objective gastric symptoms were completely submerged under the clinical picture of what looked like enteritis. This also occurred in the abnormality of gastric secretion, which he designated as "heterochylia." To recognize this dyspepsia with diarrhœa a test-meal analysis was indispensable, and stool examination necessary. Gastric peristalsis was unimpaired, but chymification absent entirely. The fæces showed unchanged residue of meat, connective tissue, especially vegetable foods, and even fat residue. He referred to the work of Pavlov, and the newly discovered enzyme in gastric secretion, a specific ferment, chymaze, which did not digest food, but which accelerated the action of the ferments of the pancreatic juice. He believed that the most efficient means of counteracting dystrypsia due to pancreatic insufficiency was to bring about an appetite. Appetite was the stimulus to normal gastric digestion, and this, in turn, was the normal stimulus to healthy pancreatic secretion. He then considered the newer gastric physiology, not only because the stomach was the preparatory organ for intestinal digestion, but because the chemical processes which various foods underwent in the stomach were of far-reaching importance for the change which was to occur when the food reached the intestines. Experiments had proved the astounding fact that for every kind of food a definite gastric secretion was formed of specific composition. The mucous membranc of the stomach was capable of distinguishing between the varieties and classes of food that came in contact with it. "What is the object

of appetite?" Under the influence of psychic secretion, a gastric juice was furnished, which was more effective than that which was secreted under purely chemical stimulation of the food, *i. e.* which was taken without any special appetite. Therefore, under the influence of psychic secretion foods which otherwise would not stimulate the gastric mucosa to secretion became converted by the already psychic secretion into something else which constituted a further stimulant to the secretion of gastric juice. Revelations from Pavlov's laboratory disclosed the fact of very important relations between the various kinds of foods, permitting the conclusion that they mutually advanced or interfered with the digestion of their various constituents in the gastric chyme. These experiments had given the clue to the treatment of gastric secretory disorders, not by drugs merely, but by dietetic measures. In order that we might have good normal intestinal digestion, we should, above all things, see that the mouth and the stomach were in good condition.

Dystrypsias Due to Qualitative and Quantitative Abnormalities of Diet.—In a qualitatively unhygienic mixture of the diet, containing an excess of carbohydrates, the various bacteria and fungi would cause an excessive fermentation with the formation of organic acids, particularly acetic and lactic acids, and this would interfere with the action of the digestive secretions, especially the pancreatic, which required a certain degree of alkalinity for its action. Abnormal peristalsis was due to an irritation of the excess of organic acid, fermentation began in the jejunum, and the hyperperistalsis also began there, which resulted in hurrying the jejunal contents through the entire small intestine with great velocity; here the first evacuations represented the contents of the lower bowel, with nothing characteristic, but the following stools were highly characteristic, and gave the whole clinical picture of "jejunal diarrhœa." The recognition of these stools depended upon one's familiarity with the condition of the jejunum chyme. In distinguishing between a catarrhal and a jejunal stool, he said that, in the former, there were present epithelia and round cells derived from the mucous membrane, which were absent in the jejunal stool. The jejunal stool was rich in bile, had a slight fecal odor, and generally had an acid reaction. If dystrypsia was due to excessive carbohydrate or proteid ingestion, an exclusion of this particular class of food would be necessary. The seat of starch dystrypsia was in the small intestines; as starch was the most readily digestible substance in our diet, the appearance of an abundance of starch granules in the stool pointed, as a rule, to severe digestive disorder if the cases were chronic, the acute fermentative dystrypsias of adults excluded. In chronic persistent cases it was his custom to exclude all starch from the diet. The presence of meat fibers was always significant of abnormal intestinal digestion, and if the nuclei in the muscle fibers were very evident, it signified that there was an abnormality of the pancreatic secretion. The presence of an excessive amount of undigested connective-tissue fibers, when scraped raw beef had been taken, justified him in the conclusion that the gastric digestion was imperfect. Therefore, the presence of an excessive amount of connective tissue pointed to an abnormal gastric, rather than intestinal, digestion. The appearance of droplets of fat or of fatty crystals was pathological, but the appearance of fat in the form of soaps had no diagnostic significance.

In conclusion he stated that intestinal autointoxications were most effectively treated by prophylactic measures, diet, evacuation of the gastrointestinal tract, rest, and restoration of the digestive canal to normal functioning, after an exact diagnosis had been made. It had been suggested that this form of autointoxication, like exogenous poisoning, might be treated by antitoxins or antidotes. It was not impossible that we might in the future come into possession of antitoxins effective against the poisons originating within the body, but in order to accomplish this, we must first isolate these toxins, and study them outside of the organism. So far the idea of the antitoxin treatment of the autointoxications was nothing more than a hopeful suggestion.

Dr. W. W. Van Valzah said that after we exclude diseases of the blood, organic diseases of the nervous system, of the stomach, liver, pancreas, bowels, or other organs, there still remained an abnormal condition of the bowels, pure and simple, which, for want of a better term we call intestinal indigestion. For practical purposes, in every day practice, he had found the simple classification based on the different kinds of food satisfactory, that is, intestinal indigestion due to an excess of animal or of starchy food and sugars, or of the fat foods, or an excess of the accessory articles of diet, such as tea, coffee, and condiments. The intestinal indigestion caused by animal foods was usually shown by excessive indican, foul stools, muscle fiber or connective tissue cells in the stools, and by a greater or less degree of putrefactive toxæmia. This form was best treated by materially lessening of the animal foods, or entirely stopping them for a short time; by lavage of stomach and bowels, which was very helpful in all forms of intestinal indigestion, but, unfortunately, the patients would refuse to make use of it; by giving small doses of calomel, 1-40 to 1-10 of a grain, one to four times daily, or protoiodide of mercury 1-20 to 1-10th of a grain one to four times a day. Or else ichthyol two to 4 mms. two to four times daily may be given with benefit. The intestinal indigestion due to starchy foods and sugars, was commonly made evident by gases in the large and small bowel in excess and by looseness, or constipation, and in some cases by headache. The diminishing or temporary stopping of the starchy foods and sugars was indicated, and ichthyol was beneficial, as also was salol, soda bicarbonate, and calcined magnesia. Intestinal indigestion due to fat foods was shown by excessive gases, by pain or burning, or a sense of unrest in the bowels, and possibly by fat in the stools, and, in many cases, by a passively congested liver. This congestion of the liver, he said, might be present in all forms of intestinal indigestion, but was more often met with in those forms due to faulty digestion of the fats in animal foods. In this form fats must be lessened or stopped for a time, the stomach washed out, if possible, and the engorged liver overcome by very small doses of mercurials, and alkalies, such as vichy, mild laxatives and the free and generous use of pure water internally. Sufficient water should be used in all the forms to keep the urine down to the normal specific gravity. If the intestinal indigestion was due to the accessory foods all that was necessary was to lessen or stop these foods. If diarrhœa was a feature it was to be treated with the bismuth salts, by prepared or precipitated chalk, by tannin, tanigen, tanalbin, etc. If constipation was present, the mildest remedies or measures which would bring about one daily formed movement should be used. All the forms of intestinal indigestion required the regulation of the daily life, as to sleep, rest, exercise, bathing, clothing, etc., and finally, that which was so often disregarded, a happy, hopeful, health-giving, health-expecting mental state.

Dr. Morris Manges agreed with Dr. Hemmeter in urging that the knowledge of the abnormal processes in the intestines would be increased by a study of the physiological processes, rather than by paying attention to treatment alone. If Pavlov's investigations on the stomach had shed so much light upon the functions of this organ, he asked what might be expected in the near future with regard to the much more important and complicated processes going on in the intestines? He cautioned against arranging the clinical classification too rigidly. Intestinal indigestion was not referred to separately as a disease in the textbooks of Boas and of Rosenheim, and in the monumental work of Nothnagel only five pages were devoted to its discussion. In fact, Nothnagel stated that

it would be discussed individually under each disease, since it was a symptom, rather than as a separate disease.

In considering Hemmeter's and Adler's new ferments in the saliva (chymaze), he thought it would be well to recall the experimental evidence of the nervous effects of mastication upon the secretion of gastric juice, especially Richet's celebrated case of complete stricture of the œsophagus. He thoroughly agreed with Hemmeter in his views upon the limited value of the ferments, and referred to the difficulty of convincing physicians upon this point. The psychical influences upon the secretion of gastric juice, he considered of great importance in explaining the variations of hydrochloric acid, especially in neurasthenic cases.

Dr. Weber's paper he considered of value in once more directing attention to the important etiological factor of faulty intestinal indigestion in diseases of the kidneys and arteriosclerosis. Possibly this would explain the early occurrence of arteriosclerosis in the young, where no other cause could be determined. Dr. Manges also discussed the researches of Nicholl, of the McGill University, by whom the entire subject had been presented, both from a pathological and the clinical side. Much of the data presented by him emphasized the importance of the gastro-intestinal tract in the etiology of chronic nephritis.

Dr. George B. Fowler said that the study of the psychic influences over the intestinal juices in the dog originated in this country.

Dr. Max Einhorn took Dr. Hemmeter to task for using the word "dystrypsia." He gave the derivation of the word "dyspepsia" showing that it had nothing to do with "pepsin" as was intimated by Dr. Hemmeter. Dystrypsia, in his opinon, was too narrow a word, meaning difficulty in trypsin digestion, leaving out of consideration the other pancreatic ferments. The term "heterochylia" he believed to be a good one.

Dr. Beverly Robinson believed a thing of considerable importance was experience of each individual with regard to certain treatments which the individual had tried to follow up in the march onward of science. As regards disinfection of the intestinal tract, he referred to the following three things: (1) good charcoal; (2) salts of bismuth; (3) minute doses of creosote when properly given. He asked that such combinations of food be given that would touch the palate of the patient, for he believed that unpalatable food would not be digested properly.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held December 15, 1902.

Alexander Lambert, M.D., President.

The Rational Treatment of Tetanus.—Dr. W. H. Luckett presented a brief report on this subject. He said that if one accepted the theory that tetanus germs produced their toxic effect at the point of introduction into the cord, then it was certainly most rational to resort to subarachnoid injections of antitoxin. Three cases were reported. The second case received eight injections, varying in quantity from 8 to 15 c.c. This patient received a total of 92 c c., and 159 minims of cerebrospinal fluid were withdrawn. In the third case five injections were given, and a total of 59 c.c. Altogether 532 minims of cerebrospinal fluid were withdrawn.

Dr. A. V. Moschcowitz was invited to discuss this subject. He said that he had been engaged in collating the work that had been done on tetanus, and had made some experiments with the introduction of the antitoxin directly into the brain. He thought, however, the method that had been so successfully employed by Dr. Luckett was superior, and he would give it a trial at the first opportunity.

The Modern Treatment of Urethral Strictures.—This was the subject for special discussion.

Introduction. Dilatation of Strictures.—Dr. J. W. S. Gouley introduced the subject by saying that urethral strictures were less frequent than they were thirty years ago, and this was not to be wondered at when one recalled the caustic injections employed in those days. After a brief historical sketch, the speaker took up the subject of dilatation. He laid down the following general principles: (1) Strictures at the meatus, being ordinarily dense, require incision; (2) strictures in the scrotal region which are narrow, indurated, resilient, and refractory to treatment, require internal incision; (3) strictures which render catheterism difficult or dangerous ordinarily require internal incision, if in the scrotal region, and external incision if in the perineal region; (4) strictures in the perineal region which are narrow or refractory to divulsion require external incision; (5) strictures in the perineal region, which are narrow and complicated with fistulæ, and accompanied by masses, require external incision; (6) strictures in the perineal region complicated by abscess formation or with extravasation of urine, require immediate external incision; (7) traumatic strictures in the perineal region require early external incision, and (8) other urethral strictures are generally amenable to dilatation, or at least to divulsion. Continuing, the speaker said that the principal modes of dilatation were: (1) Gradual; (2) continuous, and (3) rapid dilatation. Gradual dilatation was indicated in the formative stages of stricture, and also in long neglected cases with involvement of the upper urinary organs when a bloody operation was likely to prove fatal. It should be remembered that the restoration, as nearly as possible, of the urethral substance was essential to a proper cure. In the early stages of strictures due to urethritis they could be permanently cured in a few months by simple dilatation, but with a long-standing callous stricture many months or years of dilatation would be required. Continuous dilatation was indicated in narrow strictures, which do not yield to ordinary dilatation and threaten to cause retention of urine. This term implied the retention in the urethra of a proper instrument for a few hours or for one or two days. It was only a preparatory step to other operative measures, and should not be employed longer than three days at the most. The continuous dilatation of narrow strictures was ordinarily effected safely by first passing in a soft instrument of smaller caliber than the stricture, and allowing it to remain for six or eight hours, and then replacing it by a little larger instrument, and so on. Rapid dilatation was indicated in those narrow strictures which threaten to cause retention of urine. By this term was meant the increase of the caliber of the urethra to the extent of three or four numbers at each sitting, the sittings being two days apart. The speaker did not favor violent divulsion. Periodical dilating catheterism, he said, was essential, not only after gradual dilatation, but after divulsion and urethrotomy.

Internal Urethrotomy.—Dr. L. W. Hotchkiss read this paper. He said that strictures at or near the meatus were best divided on the floor of the canal by a bistoury under the guidance of the sight as well as touch. The Maisonneuve urethrotome was specially suitable for the narrow strictures which would admit only of the passage of a filiform guide. The Otis urethrotome found a useful field in strictures of a larger caliber, and sometimes to complete the operation begun with the Maisonneuve instrument. The Otis instrument, if properly used, would cut completely and accurately through strictures. It had been claimed that the urethrotome was a dangerous instrument, but this was equally true of the steel sound in careless hands. He had always made it a point to exercise the greatest care in accurately locating each stricture before attempting its division. When the stricture was situated at a point 4½ to 5 inches from the meatus, that is, in the region of the bulb, he was accustomed also to do perineal cystotomy. The bulbo-membranous portion of the urethra was a dangerous area,

in that it constituted a "dead space" as to drainage, and general surgical principles required that all such dead spaces, which could not be obliterated by sutures, or by the healing by blood clot, should be drained. After drainage for a few days the perineal opening should be allowed to close. Through this opening it was possible frequently to irrigate the urethra when this seemed necessary. After the first few days a steel sound should be passed into the urethra at short intervals. The dangers from internal urethrotomy were: sepsis, hemorrhage, urinary suppression and distortion of the penis at the site of the operation. The writer felt no hesitancy in saying that a well-planned and well-executed internal urethrotomy was often followed by permanently good results, and that many of the deeper strictures often treated by internal urethrotomy could frequently be effectively treated by dilating internal urethrotomy combined with perineal drainage, as already described.

External Perineal Urethrotomy.—Dr. PARKER SYMS read this paper. He said that this operation in cases of impassible stricture with retention of urine was safer than aspiration or puncture of the bladder. While the operation was comparatively simple when done with a guide, it was often most difficult when no guide was available. In performing external perineal urethrotomy with a guide, the urethra should be opened in front of the stricture, a narrow bistoury introduced on the guide, and the stricture divided, and the urethra for a short distance behind it; then a large catheter should be passed into the bladder, and the latter emptied and irrigated. Next, the meatus should be divided to its full size, and then with the urethrotome all anterior strictures should be cut. A full-sized sound should be passed through the urethra into the bladder. After thorough irrigation, a large-sized rubber perineal drainage tube should be passed into the bladder and fastened in the wound, and gauze packed around the tube. An ample gauze dressing and a T-bandage completed the dressing. If no guide could be passed through the stricture, a staff should be passed down to the stricture, the urethra opened in front of the stricture, and silk loops introduced as guides. A careful search should then be made for the opening, and when this was found, a tunneled catheter or a grooved director should be passed into the bladder. The stricture is then divided and the operation completed as already described. It was desirable to employ continuous drainage for five or six days. On the fifth day a full-sized sound should be passed through the entire urethra, and this passage of the sound should be repeated at gradually lengthening intervals. In cases of sudden retention, due to prostatic obstruction, followed by instrumentation and consequent injury to the urethra, external perineal urethrotomy should be done, and subsequently perineal prostatectomy.

Dr. JOSEPH D. BRYANT said he had never been a believer in indiscriminate internal urethrotomy. He avoided free division of the meatus, simply cutting this opening sufficiently to allow of the introduction of the necessary instruments for the treatment of the stricture. Continuous dilatation was a method which he regarded very highly, but in using it the condition of the urethra, of the bladder, and of the patient should be taken into consideration in determining how long the process should be kept up. Rapid dilatation he had only employed occasionally, and he had never looked upon divulsion with favor. A free incision appeared to be safer. In external perineal urethrotomy, without a guide, success would usually be achieved if sufficient patience were exercised.

Dr. JOHN F. ERDMANN was of the opinion that the use of the Oberlander dilating instrument was more convenient, and inflicted less pain. It was his custom to dilate 2 to 4 mm. at each sitting, the intervals being four or five days. He was in favor of continuous dilatation when it was demanded, but in cases that he had seen that threatened to require this procedure, relief had been afforded by the warm bath for from fifteen to thirty minutes. In a recent case of hemorrhage following internal urethrotomy he had found adrenalin chloride a valuable aid. In doing external urethrotomy without a guide, he favored the operation advised by Dr. Bolton. The patient is placed in the reversed Trendelenburg posture, and an incision made from one ischial tuberosity to the other in the form of an arc. When the apex of the prostate was reached, one punctured and made a dissection toward the membranous portion of the urethra. This procedure had been recently advocated, but had so far invariably proved successful. If the urine were not foul, it was his rule not to drain the bladder for more than twenty-four hours.

Dr. E. L. KEYES, JR., said that in the few cases in which he had been compelled to do external perineal urethrotomy without a guide he had found it very important to make use of a wide incision. By making a large external incision and cutting down upon the urethra external to the stricture, fastening two stout silk threads on either side, and splitting it up until the face of the stricture was reached, it was comparatively easy to find the opening and complete the operation. The free incision recommended by the last speaker most certainly proved useful, yet it seemed to him an unnecessarily free dissection. The use of urotropin seemed to him exceedingly valuable in these cases.

Dr. FERD C. VALENTINE said he had not seen, in a somewhat extended experience, any stricture which he could not pass eventually, and having once been passed, even by the finest filiform bougie, that stricture was conquered. The method of leaving the dilatation of the stricture to the patient was, in all but a few instances, reprehensible. He was strongly in favor of the treatment by dilatation, as compared with operative measures.

Dr. WILLIAM A. SHUFELT spoke of a case of retention of urine from enlarged prostate, which he had just seen, and which had impressed upon him the wisdom of resorting to perineal section promptly, rather than indulging in prolonged attempts at the introduction of instruments, through the urethra into the bladder.

Dr. ROBERT NEWMAN said that up to seven years ago he had successfully treated, by electrolysis, over 2,000 strictures of the urethra. The electrical current by its chemical action, absorbed the pathological conditions, causing the stricture. In more recent years the number of cases of urethral stricture so treated had increased, and, including cases in hospital practice, might be estimated at 2,400 or 2,500. Relapses never took place, and patients could be found in this city who had remained well as long as twenty-six years after this treatment. In 1883 he had compiled 1,755 cases from various sources, which had been successfully treated by fifty-four operators. By a resolution at a meeting of the American Electrotherapeutic Association in 1892, a committee was appointed of his peers to investigate the statistics on this subject that he presented. This committee worked diligently for one year, investigating the cases, interviewing the patients and physicians and investigating the documents submitted. This report, which was published in the Transactions for 1893, over the signatures of Drs. A. H. Goelet, W. J. Morton, and W. J. Herdman, said: "We have examined the records of Dr. Newman's cases of urethral strictures, submitted to us, and regard his conclusions as well sustained by the statistics he has presented, and, as far as our experience in this line of work adds further testimony, it is confirmatory of the value of the continuous current in resolving a large class of urethral strictures. The committee made diligent efforts during the year to comply with the directions given them, to enlist the coöperation of surgeons of large experience in other methods of treatment of urethral stricture in examining both the patients and the statistics, but failed to receive such assistance from them." Continuing, Dr. Newman said that one of the reasons that internal urethrotomy would not restore the caliber of the urethra was that incisions healing by first intention could

not make the urethra larger, while if the incision was kept apart and dilated the gap would be filled up by granulation. thus forming a cicatrix which would make the condition worse than before. Many authorities had admitted that internal urethrotomy was a wrong procedure, and he was greatly pleased to hear Dr. Gouley say that he, too, was against this operation. True, internal urethrotomy might succeed in some light cases, the mucous membrane being only a little contracted, but it would not cure an organic stricture when the surrounding tissues were pathologically infiltrated. If time permitted, it would be easy to cite many authorities as opposed to internal urethrotomy. Dilatation was an ideal treatment for the cure of that class of cases described by Dr. Gouley. In this connection he would say that he had found Dr. Gouley's tunnelled sound so useful that he had adapted it to his work in electrolysis.

Dr. Gouley said that when a urethra would admit an instrument, No. 20 French, there was no need of a cutting operation, for such a stricture would prove amenable to dilatation. If the surgeon would be careful to make the incision in *front* of the stricture in cases of external perineal urethrotomy without a guide, he would have no great difficulty in finding the opening of the stricture. He was horrified at the suggestion of making an external perineal wound for the purpose of draining a foul bladder, for this could be done effectively through the urethra. He had done internal urethrotomy comparatively few times, perhaps only fifty altogether, although much younger surgeons had reported internal urethrotomies by the hundred. In none of his internal urethrotomies had there been severe hemorrhage.

Dr. Hotchkiss said that he had learned the method of perineal drainage in Bellevue Hospital, where he had seen it very extensively and very successfully employed. It had proved exceedingly useful in the severe cases ordinarily met with in hospitals.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Held November 12, 1902.

A Case of Quartan Malaria, with Demonstration of Specimens.—Dr. F. C. Wood demonstrated some slides of parasites of quartan malaria at different stages of their development. He said that he called the attention of the society to the specimen because in his experience these cases were exceedingly rare in New York. He personally had never seen a case before; the specimens which he had seen had been obtained through the kindness of the Johns Hopkins Hospital staff. The patient was an Armenian, about thirty-five years of age, who had been in New York for the past two years. While in Asia Minor he had suffered for several years with irregular attacks of fever. During his residence in this city he had also had attacks of fever at irregular intervals, the attacks lasting usually for two or three weeks, and being then followed by a period of comparative health. He had taken quinine, but without the supervision of a physician. The present attack had lasted for about three weeks. The patient had a chill regularly every fourth day, beginning at 11 o'clock in the morning. He had an enlarged spleen, and very marked anæmia, the hæmoglobin being about 50 per cent. The blood at the time of the beginning of the chill showed very beautifully the characteristic rosettes of the quartan parasite. None of the rosettes seen had more than nine merozoites. In fresh blood the morphology was even better than that in smears, and the segmentation was watched a number of times on a warm stage. Very marked phagocytosis was present under these conditions; but there was no evidence of flagellation, though there were a considerable number of gametes in the specimen. The patient was watched through two complete cycles, and it was found that there was only a single group of organisms. The preparations were stained with the Wright modification of the Jenner stain, which had, in the hands of the speaker, proved a very useful method of staining the chromatin of malarial parasites, though the results were not so perfect as those obtained by the use of the Nocht method. By this chromatin stain two types of gametes could be made out, one form in which the chromatin was collected into small masses in one portion of the parasite, and the other in which the chromatin was in the form of fine dust-like particles. In the presegmenting forms double rods of chromatin in each segment were easily seen, just as has been figured by the Italian observers. Occasionally the red cells showed degeneration, but the cells harboring parasites showed none of the peculiar degeneration which is so frequently seen in cells infected with the tertian organism. In this case all infected cells were small and dark, in contrast to the large swollen red cells of the tertian infection. There was a relative increase in the large lymphocytes, but no other changes were noticed in the white cells.

Dr. Ewing said that he considered this specimen a very beautiful demonstration of quartan rosettes, and one that a New York observer very rarely encountered.

A Case of Mixed Quartan and Estivoautumnal Malaria.—Dr. James Ewing presented this case because of its great rarity, it being the first case of quartan infection he had seen in a ten years' study of malaria. The patient was a man who had been sent to British Guiana in July, 1902. He returned in September, broken in health, with a history of irregular illness without distinct chills. No distinct chills occurred during the time he was under observation in New York, which was for about a week. A few typical quartan parasites were found in the blood smears, and in a subsequent review of the slides crescents were found. This case was therefore to be regarded as one of mixed quartan and estivoautumnal malaria.

Dr. George P. Biggs said that quartan malaria was very rare in New York, and that he had never been able to convince himself that he had really seen a case.

A Melanoma in a Cow.—Dr. James Ewing presented this specimen for Dr. V. A. Moore of Ithaca. The case was one of great interest on account of the extent of the tumor growth. There was no history. The growth was primary in the breast, there being a very considerable mass of tumor in that region. The exact location could not be made out, but on the skin there were a few pigmented spots from which the original growth may have sprung. There was a very large mass in the udder, which measured ten by six by five inches. The center was softened. From this starting point all the viscera of the animal were extensively affected. The liver was very large, and showed very distinctly the relation of the tumor to the liver parenchyma. A most interesting feature was the manner in which the growth passed along the superficial lymphatics of the diaphragm. At the tendinous edge there were several large cauliflower masses, very densely pigmented; while along the tendinous fibers were thin elongated masses, coal-black in color, apparently distending the superficial lymphatics. The heart was riddled with small nodules of melanotic tumor. Beneath the periosteum of the ribs there were large diffuse tumor masses. The microscopical structure was similar to that which is seen in the human subject. The cells in the secondary growths were almost all fusiform and richly pigmented. The original point of development was not found. Dr. Ewing said that he was inclined to accept the belief of Unna, Marchand, and others, that these tumors were, in a large majority, epitheliomata arising from the basilar cells of the Malpighian layer of the skin, and showing very atypical cell forms in the metastases. In a series of melanomata he had found some which showed very distinctly that the beginning of this process was well within the epithelial layer of the skin, from which foci there was a proliferation of the cells into the derma. From this point the cells became atypical, and epithelial characters were not retained.

Dr. George P. Biggs said that the presentation of this

case had been extremely interesting to him, particularly the remarks on the nature of these growths. He had himself come to the same conclusion, as the result of a specimen examined in which the growth was studied in early development. There were very clearly shown in some places branching columns of epithelial cells working down into the deeper tissues, and the tumor, as a whole, had an alveolar arrangement. He had diagnosed the case as of epithelial origin. The tumor had originally occupied the outer surface of the arm, and the metastases removed several weeks later from the axilla had the appearance of pigmented embryonic connective tissue growths; but taking the primary lesion into consideration, one was forced to the conclusion that these irregular cells of the secondary deposits were also of epithelial origin.

Dr. EWING said that the name melanoma was used by Virchow, who gave it in order not to define his position more fully. He said he had recently been shown some sections of embryonic eyes in which the pigment cells of the choroid could be demonstrated as continuous with the retinal epithelium, and, therefore, evidently of epithelial origin. This relation, however, was denied by most ophthalmologists. One of the chief arguments against the epithelial origin of melanomata had been that very similar tumors were found to develop from the "connective tissue" cells of the choroid. It would be seen, however, that if the choroid cells themselves were derived from epithelium the argument lost one of its chief supports.

A Meningocele.—Dr. JAMES EWING presented for Dr. OTTO H. SCHULTZE a specimen of meningocele, which had been obtained from a child whose body had been taken to the morgue, and in which the protrusion included almost the entire cerebellum.

Dr. HARLOW BROOKS said that about two years ago he had seen a similar case in which the meningocele contained the greater part of the right lobe of the cerebellum, and a small portion of the left lobe. The mass had been removed surgically. The child lived for nearly a month after the removal, and finally died of pneumonia. The mental status was very low. He was probably idiotic, but as he was but four months old this could not be definitely determined. At the autpsoy a condition was found similar to that shown, except that the cerebellum was almost completely removed.

Observations of Adrenalin Glycosuria, and Certain Relations between the Adrenal Gland and Carbohydrate Metabolism.—Dr. C. A. HERTER presented a paper on this subject. It had been known for some time that extracts of the sheep's suprarenals were capable of inducing glycosuria in dogs and rabbits when injected subcutaneously. Dr. Herter found that after the injection of solutions of adrenalin chloride into the peritoneal cavities of dogs a marked glycosuria developed, the percentage of sugar ranging from 3 to 10 per cent. This gradually wore off, and in the course of thirty hours the glycosuria had disappeared. The glycosuria produced by subcutaneous injections of the same dose or by the same dose given by the stomach was much less. Intravenously a moderate glycosuria could also be obtained, but it was not of so high a grade as when the dose was given intraperitoneally. In glycosuria caused by adrenalin the amount of sugar in the blood was distinctly increased above the normal, in this respect resembling the diabetes of the human subject. An interesting fact developed by Dr. Herter was that when applications of adrenalin were made to the pancreatic gland itself it was possible to call forth a large amount of sugar by the use of a small amount of the drug. These results were dependent in all probability upon excessive conversion of glycogen into sugar, this conversion taking place in the liver, as it had been shown that the blood in the hepatic vein contained much more sugar during the treatment than the blood in the portal vein. The action was probably through the nervous system, for if one collected the blood from the pancreatic vein after painting with adrenalin and injected it into the blood of a normal animal, one got only trivial glycosuria. Reducing agents also caused glycosuria when applied to the pancreas. Four things were observed which led to the opinion that the suprarenal gland influenced carbohydrate metabolism in an important way. One was that intermittent massage of the suprarenals was followed by glycosuria. Another was that extirpation of both adrenals was followed by a fall in blood sugar. The third was that adrenalin failed to induce glycosuria when injected intraperitoneally into dogs from which the adrenals had been previously removed, or in which the adrenal vessels had been tied. Finally, it was found that the onset of glycosuria after extirpation of the pancreas was delayed by previous extirpation of the adrenals. This inhibitory effect was only temporary. Dr. Herter at first interpreted these facts as meaning that the phenomena observed were due to chemical derangements connected with an excess or diminution of an adrenal internal secretion. It now seemed likely that many of the phenomena were really of nervous origin, and further work was necessary to decide whether the internal secretion hypothesis was tenable, and if so, to what extent.

Dr. EWING said that he felt that these studies furnished a very large amount of information on the subject. He would many times have liked to stop Dr. Herter to ask questions, make suggestions, and put various queries. He felt that a paper of this sort could be discussed only at great length, and only by those who were intimately familiar with the subject; and that, therefore, the amount of discussion which such a paper would bring forth must be tatally inadequate to the value of the paper. It seemed to him that if Dr. Herter had succeeded in showing that an injection of adrenalin extract produced glycosuria; that the application of the substance to the surface of the pancreas produced glycosuria; that compression of the adrenal gland produced glycosuria, while compression of other abdominal structures did not; that tying off the vessels of the adrenals rendered it impossible to produce glycosuria by ordinary means; that if, after extirpation of the pancreas, the glycosuria was diminished by tying off the adrenals, he had a considerable volume of evidence to show that the adrenal was very important in the pathology of human diabetes.

Dr. HERTER said he realized very well that unless the members of the society had a chance to think over the facts brought out it was unsatisfactory to enter into a discussion. He felt sure that the facts would stand the test of subsequent observations, but as to the construction to be put upon them he could not speak confidently. It looked to him as though it were safe to assume that the suprarenals exerted a marked influence on carbohydrate metabolism. He was at first inclined to put a chemical construction on all the facts, but on more careful consideration had come to the conclusion that he was not justified in doing this without further data. Dr. Herter thought his experiments should show whether or not the blood passing through the pancreas was in any way changed so that its sugar was converted into something else in preparation for the process of storing in the liver. The study of carbohydrate metabolism was very complex. There could be no doubt that all active metabolism of the body was closely connected with sugar combustion. More than one-half of the energy of the body came from sugar. The question was not limited to the pancreas or adrenals or nervous system. It was something that concerned every tissue in the entire body.

Vacancies in the Army Medical Corps.—There are thirty-five vacancies in the grade of Assistant Surgeon in the army, and there is little prospect of filling them until Congress shall have revoked some of its unwise legislation in the matter of the rank and prospects of army surgeons. The next examination to be held in Washington will take place some time in April, and an examination is now being conducted in the Philippines to fill some of the places.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 27, 1902:

	Cases.	Deaths.
Measles	127	10
Diphtheria and croup	356	43
Scarlet fever	135	4
Smallpox	..	..
Varicella	87	1
Tuberculosis	245	148
Typhoid fever	75	18
Cerebrospinal meningitis	..	2

The Gas Evolved in the Decomposition of Hydrogen Dioxide by Pus.—John Marshall concludes his paper as follows: It seemed that possibly the bactericidal action of hydrogen dioxide might be due to its penetrating the cell membrane of the bacterium, and coming in contact with some body contained in the bacterium, which possessed the property of decomposing hydrogen dioxide, liberated the gas which, by its physical action, ruptured the membrane, thus destroying the vitality of the bacterium, but experiments made with the bacillus megatherium, bacillus anthracis, and the yeast-cell did not appear to substantiate the thought. Von Bruns, in recommending the use of hydrogen dioxide in the treatment of infected wounds, attributes its action as being partly physical and partly chemical. It certainly has a physical action in mechanically loosening and disintegrating necrotic matter, and probably also a chemical action, due to the liberation of oxygen in the nascent state, in the production from noxious substances of new compounds which may be innocuous in character. Use is made of its physical action as first suggested by Crile (Browning), in mechanically removing the particles of carbon in gunpowder burns, which, after the healing of the wound, give a bluish-black appearance to the skin. It might also be found useful in removing the particles of coal which produce the bluish-black stains in the wounds of workers in coal. It is unlikely that absorption into the circulation of a quantity of the solution sufficient to produce gas emboli occurs when it is employed in the treatment of wounds and cavities, provided openings exist for the free escape of the gas, so that no pressure is exerted on the liquid.—*University of Pennsylvania Medical Bulletin.*

Congenital Hydronephrosis.—G. N. Acker reports two cases of this condition, which is certainly not a common one. It is due to congenital malformation at some point in the urinary channel, which may consist in phimosis, stricture of the urethra, valve-like insertion of the ureter in the bladder, or an abnormal insertion in the pelvis of the kidney. In some cases the cause cannot be demonstrated even on autopsy. Distension of the abdomen is a prominent feature in congenital hydronephrosis; the veins of the abdomen are enlarged, and the skin has a pale, smooth, shiny appearance. By compression of other organs various complications arise, such as constipation, vomiting, dyspnœa, and palpitation. Complete anuria may suddenly occur. Constitutional symptoms and local pain are absent, as far as can be ascertained. This condition has been mistaken for sarcoma of the kidneys. Double hydronephrosis often presents the appearance of tuberculous peritonitis. Ascites is also suggested by the uniform swelling of the abdomen and fluctuating character of the growth. Aspiration of the fluid will usually settle the doubts as to the nature of the swelling, for it is free from blood and pus, and commonly contains urinary constituents. The course and termination of this disease is rapid and fatal. Death results from uræmia or some complication. No treatment is of any avail in cases of true congenital hydronephrosis.—*Washington Medical Annals.*

Nitrogen Excretion in Pneumonia, and Its Relation to Resolution.—Henry Wireman Cook gives the following summary of his work on this subject: (1) In cases of pneumonia a surplus amount of nitrogen must be excreted during the days of resolution that will correspond at the least to the original quantity of exudate poured into the involved lung. In most cases there is more, the rest representing in great part a continuation of the formation and an absorption of the inflammatory exudation, plus other tissue destruction. (2) In cases of marked delay in resolution the continued high nitrogen output indicates a continuation of the local inflammatory process, so that in those cases of several months' persistence we might speak of a chronic pneumonia. (3) In cases of rapid resolution the leucocytosis curve follows the curve of nitrogen excretion with a very striking parallelism, and would seem to point to a causal relation between leucocytes and resolution.—*Bulletin of the Johns Hopkins Hospital.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending December 27, 1902:

A COMPARATIVE STUDY OF THE ROUTINE TREATMENT OF CERTAIN DISEASES IN FOUR OF THE LARGE NEW YORK HOSPITALS.*

BY HENRY P. LOOMIS, M.D.,
NEW YORK.

THE personal equation is a most important factor in practical therapeutics—more so than in any other branch of medicine, and tends so directly to influence results that it is most difficult to attribute these specifically to any routine treatment.

In our large metropolitan hospitals we may look more than anywhere else for the most advanced methods of treatment, as here every new suggestion in therapeutics is tried, weighed, discarded, or adopted. Accurate statistics are kept, thus furnishing data for approximately reliable and impartial conclusions, and all under the critical eye of the young and enthusiastic members of the house staff who, before their two years are up, are well able to determine the treatment producing uniformly the best results. Therefore, in the large hospitals I should say we can find, if not the best plan of treatment, certainly the one that is accepted by the majority of the profession as giving the best results. I have taken for comparison four of the largest hospitals in New York: The Presbyterian, Roosevelt, New York, and Bellevue (second division).

On the visiting staff of these four institutions are some of the ablest men in the profession, certainly men with large practical experience. As the medical service in all these hospitals rotates, the criticism might be offered that the treatment would change as each new visiting staff comes on duty, in accordance with their personal ideas. This I have found not to be the case to any extent. After a talk with the present house staff of all these hospitals, I find that there is in each institution what might be called a routine treatment for most of the common diseases, based upon past experience and drawn from the most effective suggestions of the various visiting physicians. Upon investigation one finds a fairly unchangeable method of treatment, which can be compared to a composite photograph, being the final result of many years experience and experiments—superimposed and assimilated.

The details of treatment in the various hospitals differ distinctly if not radically. However the statistics of results compare favorably one with another.

I have restricted comparison to only a few diseases, such as typhoid fever, pneumonia, pleurisy with effusion, etc., because hospital treatment, as at present practised, shows the best results and the lowest mortality in these diseases. A mortality lower in spite of the large number of unfavorable cases, than that obtained in private practice. Again these diseases present the same types or run the same course as they do in patients in private practice, which cannot be said of many other diseases seen among hospital patients.

The hospital treatments which I shall speak of will differ somewhat from the treatment we each might carry out, but it will certainly represent the prescribed treatment of the majority. To obtain the details of treatment from the different hospitals, I had typewritten a careful series of questions. These were answered in writing by the different house physicians; then personal interviews with the medical staff of each hospital were had, and I found that in many instances one or more of the visiting staff had verified the answer to the questions and had added elaborations of their own. I also found that more variation in the ideas of the visiting physicians occurred in Roosevelt Hospital than in the other hospitals.

Typhoid Fever.—The mortality from this disease, during the last two years, as furnished by the statistics of the four hospitals, is practically the same in all, namely, 10 per cent. This is as low a death rate as has been reported in any of the large hospitals of the world.

Murcluson reported, in England, in 27,000 cases of typhoid fever, a death rate of 17.45 per cent. Jaccourd, in France, in 80,000 cases, a mortality of 19.23 per cent. Seventeen thousand cases in Vienna showed a mortality of 22.5 per cent.

The principle continental hospitals have a mortality varying between 16 and 25 per cent. Some years ago Dr. Delafield collected from the records of the New York hospitals, extending over a period of five years, 1,305 cases with a minimum mortality of 20.1 per cent.

To the present treatment of this disease must be given the credit of saving over 50 per cent. of the people who formerly died, for the disease certainly does not average any milder type now than it did ten or twenty years ago.

To the Brandt Bath is rightly given a great deal of credit for this decrease in mortality, but to my mind as much credit is also due to the careful nursing now in vogue, to the strict attention to details in the general management of the cases, to the care in diet, and, lastly, and of great importance, to the reaction from dosing.

Watching typhoid fever in the hospitals, one is impressed with how seldom drugs are used now as compared with the past, and how they are only given when absolutely necessary to meet conditions that cannot be corrected by any other way.

The best illustration of this is now seen in the controlling of most cases of diarrhœa and abdominal distension by restricting the diet to milk, modifying the milk if necessary, and not considering the diarrhœa an essential symptom of the disease to be controlled by opiates and intestinal antiseptics, as formerly.

The details of the treatment are nearly the same in all respects in the different hospitals. Only in four things does there seem to be any material difference of opinion: (1) Whether the diet shall be

*Read before the New York Clinical Society, November 28, 1902.

exclusively milk or not. (2) When and how the diet shall be modified at the end of the disease. (3) What temperature of the patient shall call for the giving of the Brandt Bath. (4) The question of giving the Brandt Bath in every case.

I will ask your consideration of these four differences more in detail:

First.—The Diet in Typhoid Fever. Milk is the exclusive article of diet during the whole course of the disease in all the hospitals except the Presbyterian; there they give besides milk, beef tea, chicken broth, egg albumen, and varieties of wheaten food. The milk is always modified with lime water or vichy and sometimes peptonized. At Roosevelt Hospital, only during the service of one visiting physician, besides the milk, broths (chicken, beef, or mutton) are used. At the New York Hospital the milk is often modified by adding cerium oxalate (gr. v), sod. bi-carb. (gr. x) to milk (℥ viii).

Second.—When and How the Diet Is Modified at the End of the Disease: This is the one point of greatest difference in the various hospitals, and is the one point on which the different visiting physicians of the same institution do not agree. At Bellevue and Roosevelt hospitals no change is made in the milk diet until the temperature reaches normal. At the Presbyterian Hospital the first day the temperature is under 100° milk and toast and soft boiled eggs are given. At the New York Hospital when the temperature begins to fall, if the patient complains of hunger, beef juice is given. At Roosevelt Hospital Dr. Delafield gives beef juice and scraped beef only in protracted cases, before the temperature reaches normal. Dr. Thomson gives scraped beef when the temperature has not reached 100° for three days. At Bellevue Hospital the patient is generally kept on milk diet for from four to six days after the temperature has reached normal. In the majority of the hospitals, as soon as the temperature reaches normal, the diet is changed as follows: Milk toast, broths (plain), raw eggs in milk, soft boiled eggs, beef juice ℥ i, scraped beef sandwich, then chops, and, later, baked potatoes, after four to seven days of normal temperature.

Third.—Giving the Brandt Bath to Every Case. At the Presbyterian and New York hospitals all cases "are tubbed." At Bellevue Hospital many cases in which the temperature can be kept below 103½° by alcohol sponging, the Brandt Bath is not given. At Roosevelt Hospital the bath is given in nearly all cases running a temperature above 103°. Drs. Delafield and James use the tubs, but rarely after the first two weeks. Dr. Delafield tubs some cases with comparatively low temperature, but who are much poisoned.

Fourth.—At all the hospitals the Brandt Bath when given is ordered when the temperature reaches 103°, with the exception of the Presbyterian Hospital, when it is given for a temperature of 102.5°. At the other hospitals the only exception to the general rule is when Dr. Peabody is on duty at the New York Hospital, when he orders the baths for a temperature of 102.5°, and Dr. James, when on duty at Roosevelt Hospital, for the same temperature. Two of the hospitals (Presbyterian and Bellevue) give the baths every four hours, and two (Roosevelt and New York) give them every three hours. The temperature of the first bath in all the hospitals averages 70°. All the children are tubbed at a higher temperature, viz., 85°. The duration of the bath is fifteen minutes, and whiskey before and hot milk after the bath is universally given. The temperature is taken in all the hospitals except the Presbyterian (one hour) one-half hour after the bath.

The following is the composite treatment of typhoid fever as based upon the methods and details at present in use in the majority of the four hospitals we are considering:

Complete Treatment of Typhoid Fever.—(Composite Treatment). Based on the present treatment in four of the New York hospitals. *General management* directions are given that the patients' stools be disinfected by a solution of formaldehyde 1-40; that the personal linen and bed-clothes be soaked in a solution of carbolic acid 1-20 before they are sent to the wash; that the nurse should wash their hands in a solution of bichloride 1-1,000 after attending to the patient.

The *diet* of the patient should be as follows: (1) During the course of the disease, milk exclusively, either with lime water peptonized or prepared. (2) At the end of the disease, when the temperature has reached normal, or is running under 100°, the following articles of diet are given: soft-boiled eggs, chicken, beef sandwiches, and finally, at the end of four days, a chop can be added.

When *stimulation* is indicated by the pulse, heart action, and general condition of the patient, whiskey in ℥ ss. doses is the form used. Strychnine should only be given when whiskey is not holding the patient; it is not given as a routine practice, but more to reinforce whiskey. Digitalis is only given when there is evidence of right heart failure, as shown by the evidence of pulmonary œdema, blueness of the extremities, etc. It is better given hypodermically.

The *Brandt Bath* should be given in all cases when the temperature reaches 103°. It should be ordered every four hours. The technique is as follows:

The patient receives ℥ ss. of whiskey (diluted) before the bath and a glass of hot milk after. The temperature of the bath should be 70°, and gradually reduced by ice to 65°. The patient should remain in the water fifteen minutes and should be constantly rubbed. A cold compress or ice cap should be placed on the head. On removal from the bath the patient should be dried off by a sheet which is removed, and then the patient is wrapped in blankets. At the end of half an hour, the temperature is taken, and noted on the chart, the effects of the baths being recorded by a red line. The 4 A.M. bath can always be omitted with advantage, and in most cases the 12 P.M. bath also.

The following is the treatment for the *special symptoms* that may develop in the course of typhoid fever: (1) Headache—ice cap, acetanilid, and caffeine. (2) Sleeplessness—trional. (3) Constipation—no cathartics should be given beyond the initial dose of calomel. The bowels should be moved if necessary, only by daily enemata. (4) Tympanites—ice coil, turpentine stupes; 5 m. turpentine q 3 h internally. (5) Hemorrhage—restrict milk to small quantities, stop enemata, apply ice coil, give majendie hypodermically. (6) Perforation—operate at once.

When *convalescence* is established, the patient can be allowed to sit up in bed after the temperature has been normal one week. Can get out of bed after it has been normal ten days. Can leave house two weeks from the time patient was first out of bed. The patient is allowed to return to a regular diet three weeks after normal temperature; care, however, being exercised for six weeks in the eating of fruit.

Pneumonia.—When a patient enters any one of these four hospitals suffering from pneumonia, he is.

TABULAR ANALYTICAL TREATMENT OF TYPHOID FEVER IN SOME OF THE NEW YORK HOSPITALS.

given calomel, usually in small doses often repeated, and this is followed by a saline in the morning. The calomel is repeated during the course of the disease if necessary.

All the hospitals at the present time apply local measures to the affected lung when the pain and distress is intense. Flaxseed poultices are still used more than any other local applications. It seems to me that these applications are not used by the general practitioner as much as they are in the hospitals. In one of the hospitals an electric poultice is often used instead of the flaxseed poultice, it being much more readily applied, cleaner, and keeps a constant temperature. In some of the hospitals the pneumonia-jacket is used. The treatment of fever varies more than anything else. Some tub most of their cases with a temperature of 103° and over, when they are alcoholic and delirious, and sponge regularly q. 3 h. for ten minutes all cases when the temperature reaches 102°. This plan of checking fever is not adopted in all hospitals; 103½° is the ordinary sponging temperature. At some they wait until the temperature reaches 104°, and then use wet packs, applied to the anterior half of the body, and wrung out of water at 80°.

It is well known that the treatment of the fever in pneumonia is not now considered so important as it was formerly. We all remember the time when cold sponging, antipyretics, drugs, etc., were constantly employed to keep the temperature below 102°. Now it is believed that a short run of temperature in this disease has but little effect on cell protoplasm. Some foreign bacteriologists claim that the pneumococcus will not grow at the high temperatures (104°), while they thrive at a temperature of 102° or below, and so they advise not to attempt to reduce the fever in pneumonia.

For the very severe *pain* over the affected lung, which is so often the prominent symptom of the ushering-in stage of this disease, two methods of relief are in vogue in all the hospitals: (1) Poultices to the side; (2) Morphine hypodermically if necessary. At the Roosevelt Hospital they often strap the side, in place of applying poultices.

For the *insomnia*, which is often a distressing symptom, the one drug which is universally used is codeine in ¼-grain doses. At some hospitals it is often combined with 15 grains of trional. The next drug which is most commonly used for this condition is bromide of potassium in 20-grain doses. Three of the hospitals use codeine gr. ¼ for cough, and one uses heroin. As we all know, the critical time in a case of pneumonia begins with the evidence of cardiac failure. The first indication of systolic weakness and failure of arterial tonicity leads to the administration of cardiac stimulants. The three cardiac stimulants which are used in all the hospitals are alcohol, strychnine, and digitalis.

Of these I find the one that stands first, and on which the greatest reliance is placed, is alcohol. Always in the form of whiskey, and practically always in the constant dose of ℥ ss., the time of its administration varying from q. 4 h. to q. 1 h., according to indications.

There has been a peculiar thing about the use of the second drug in pneumonia—strychnine. Most of us can remember when we first began the practice of medicine, strychnine was seldom, if ever, given as a cardiac stimulant in pneumonia, now it is universally used. Clinical experience has confirmed what physiological experimentation has long ago proven. When we remember the physiological action of this drug, how it stimulates the heart and tones up the arterial system by its direct stimulant action on the vasomotor centers, and not like alcohol and digitalis by its action on the heart muscle and the arterial wall, we find an explanation of its effectiveness, it whips up the heart, one might say, from its powerful nerve center. Strychnine is never followed by the secondary depression so often seen after alcohol. I find this drug universally used in the hospitals. In talking over its use with the various house physicians, I learn that the two indications which call for its use are: (1) When whiskey is not able to hold the heart, they always used it, however, secondary to whiskey; to reinforce it, as it were. (2) When there is evidence of pulmonary œdema and cyanosis—here it is generally given hypodermically in $\frac{1}{20}$ grain doses. At two hospitals this second symptom is the special indication for its use. All alcohol cases were especially found to respond to the action of this drug. At all the hospitals, when, in spite of the alcohol and strychnine, the pulse became very rapid (130 and over) and feeble, digitalis was given, either m.v. of the Tr. q. 3 h. or m. ii Fl. ext. q. 4 h. This drug is not given as a routine practice, and only, apparently, when after whiskey and strychnine have both been given, the heart failure is found to be increasing.

At Roosevelt Hospital, Dr. Delafield uses digitalin $\frac{1}{8}$ mg. with aconitine $\frac{1}{8}$ mg. in cases with rapid heart action, when the pulse is not too soft, and the pulmonary circulation is good. These dosimetric granules are given q. 1 h. until the pulse drops to 100, then stopped, until the pulse reaches 112 again, and then resumed.

The only other drug that I found used in the hospitals was nitroglycerin. All the hospitals use it occasionally. Besides the pulse of high arterial tension that may call for its use in any case, cyanosis is the one symptom that especially indicates its use. At one or two hospitals it is always used when cyanosis becomes marked. At one, when œdema of the lungs develops, it is generally given. Atropine and caffeine are not given in a case of pneumonia in any of the hospitals. Oxygen is always given as soon as pulmonary œdema develops and cyanosis is marked. One change in the administration of oxygen that has been noted is its earlier use. It is not now always given as a last resort. We can all remember when we saw the oxygen tank come into the sick room, we knew the end was near; this is not so now. At some hospitals they use it often early in the disease, for labored breathing, and always when there is the least cyanosis.

I find that during the past year or so a number of drugs have been tried in pneumonia and discarded; for example, iodide of potassium in ℥ i doses a day; sodium salicylate, large doses of 240 grains a day. For the past year creosote in some form has been extensively tried. Many of the hospitals have given this remedy a trial, but, as far as I am able to learn, with no results. Antipneumococcus serum has not been used in any of the hospitals, with the exception of one ward in one of the hospitals. Here the results, as I understand them, were negative.

Acute Articular Rheumatism.—Of all the acute diseases met with in the New York City hospitals, acute articular rheumatism is the most common. Again, it is certainly more often seen in hospital practice than in private practice.

The specific treatment at the present time in vogue is a combination of the old alkaline treatment and the newer salicylic-acid treatment. In all the hospitals the stock preparation which is kept in the wards, and almost always used, is a freshly-made

combination of salicylic acid and sodium bicarbonate in equal parts. Large doses of this freshly-combined salicylate of soda are used; doses I think much larger than those given outside the hospitals. It has always seemed to me that large doses must be given to be effective. Twenty grains q. 3 h. or q. 4 h. is the average dose given. As the case improves, the frequency of the dose, but not the size, is diminished. There seems to be greater difference in the preparation of salicylic acid used at the Roosevelt Hospital than any other. For example, Dr. Delafield when on duty gives the following: Acid salicylic 9v gr. x, soda bicarb. gr. vi, ext. glycyrrhiza, powd. gr.iii, glycerin m x L, aquæ ad. qs. ℥ii, this dose is given q. 3 h. As is seen, the amount of salicylate of soda is small, 10 grains to a dose. Dr. Thomson gives strontium salicylate gr. xx q. 3h. Dr. James is a believer in the ol. gaultheria, and uses it at the Roosevelt and Presbyterian hospitals, in preference to the salicylates, in doses of m. x q 4 h. Dr. Kinnicut also uses ol. gaultheria. With these exceptions salicylate of soda is universally used, but always the freshly-made preparation.

The combination of the alkaline treatment with the salicylic acid treatment is used in all the hospitals, with the exception of Roosevelt. The preparation which is given with the salicylate of soda mixture at the Presbyterian and New York hospitals is what is known as the A.B.C. mixture: R. acetate, citrate and bitart. potass. of each gr. xv to xxx at a dose, well diluted with water every four hours. The New York Hospital varies the mixture a little by putting in rochelle salts in place of potass. bitart. At Bellevue Hospital an extra amount of bitart soda, generally 20 grains, is added to each dose of the salicylate of soda mixture. At the Roosevelt Hospital the salicylic-acid treatment is pushed from four to seven days; if then not effective, it is stopped and the alkaline treatment tried. The object of the alkaline treatment is to get the urine alkaline, and to keep it so. It is continued in decreasing doses after all joint and constitutional symptoms have disappeared and the salicylates have been stopped. I have tested a number of times how long it takes to get the urine alkaline in acute rheumatism, and I have found it very much longer that one would believe from reading the works on acute rheumatism—as it takes at least three days and often four. At Bellevue and New York hospitals asperin has been used lately as a substitute for the salicylates, with good results. The local treatment of the inflamed and painful joints vary somewhat in the different hospitals. The one preparation which is used in all the hospitals except Roosevelt is guaiacol. At Bellevue Hospital it is diluted with equal parts of olive oil; at Presbyterian Hospital, with glycerin, while at the New York Hospital it is diluted with alcohol. Guaiacol is applied to the joints on compresses, covered with rubber protective or bandages. Joints are treated at the Roosevelt Hospital by ice-bags during the early stages and later by oil of wintergreen, locally applied. A 10-per-cent. ichthyol ointment is often used at both the Bellevue and the New York hospitals. I have seen exceedingly good results at the New York Hospital by simply wrapping the inflamed joints in cloths wrung out of methyl salicylate and giving no medicine internally. In thirty to forty minutes the urine of these cases will give the salicylic-acid reaction, showing that the drug has been absorbed through the joints and eliminated. It has seemed to me often that the constitutional symptoms—fever, pain, etc.—disappear as quickly under these local applications as under internal medication. I have tried at different times over twenty cases on this treatment alone.

The diet in all the hospitals is the same during the attack—exclusively milk; not until the patient has left his bed is he allowed to have any meat. The time when it is considered advisable for the patient to get up varies somewhat in the different institutions. At the Roosevelt Hospital, as soon as the patient's temperature is perfectly normal. At the Presbyterian Hospital, a few days after a normal temperature. At the New York and Bellevue hospitals, not until the temperature has been normal for a week and all the joint symptoms have disappeared.

A number of years ago, in studying a large number of cases of acute rheumatism, with the idea of endeavoring to ascertain the causes of the relapses, which, as we all know, are so liable to occur in spite of all we can do, I came to the conclusion that two things were the most important factors in causing these relapses, viz., too early feeding and too early getting up. It seems to be that the treatment of convalescense in this disease is fully as important as the treatment of the attack. The one cathartic which is used in all the hospitals is the salines epsom or rochelle salts.

Hyperpyrexia is treated at the New York and Presbyterian Hospitals by tubs for a temperature of over 105°. No cases of a temperature above 105° have been seen at the Presbyterian Hospital during the past two years, and only one at the New York and one at the Bellevue. So the complication must be rare. Pericarditis is treated at all the hospitals by the application of an ice-bag to the pericardial space, and morphine if necessary. At the Presbyterian Hospital during the past two years fifteen cases with embarrassed respiration and a bad pulse, in whom the diagnosis of fluid in the pericardium was made, were aspirated. In half they found fluid, in one-half they did not. No bad results followed the attempts at respiration. My own experience bears out the above that the diagnosis of fluid in the pericardium is one of the most difficult diagnoses we are called upon to make.

Pleurisy with Effusion.—At only one of the four hospitals, and there only during the service of one of the visiting physicians, is the fluid removed from the chest in pleurisy with effusion at once when the condition is first diagnosed. At all the other hospitals the case is watched before aspiration, and then they only aspirate when one of the following conditions is present: (1) Large amount of fluid, causing displacement of the heart and dyspnœa. (2) Filling of the chest cavity with a large amount of fluid even if there is no evidence of cardiac embarrassment. (3) Pain, embarrassed heart action and marked prostration. (4) When the fluid remains at a fixed level for five days (P) to ten days (B) (N.Y.)

The technique of emptying the chest cavity varies somewhat at the various hospitals. The point of inserting the trocar at the Presbyterian Hospital is in the eighth interspace, just below and outside the angle of the scapula; at the New York Hospital it is usually in the ninth interspace, at the outer border of the erector spinæ. At Bellevue Hospital, two spaces below the tip of the scapula in the posterior auxiliary line.

All these points of inserting the needle differ from that usually given in the textbooks. At all the hospitals a hypodermic of a 2-per-cent. solution of cocaine is injected under the skin where the needle is to be inserted. At the New York Hospital a small cut is made through the skin

before the trocar is inserted. At Bellevue Hospital ethyl-chloride is sprayed over the point of puncture before the cocaine is injected. Personally, it has always seemed to me much less painful to introduce the trocar without all these preparations. The hypodermic injection of cocaine seems to me more painful than the quick puncture of the aspirating needle. At Bellevue Hospital the Delefeuy apparatus is used to draw off the fluid. At the Presbyterian Hospital, bottles from which the air has been exhausted by a pump. At the New York Hospital a trocar and cannula with a long rubber tube is employed, an artery clamp is put on the upper end of the tube and the air forced out, then another clamp is put on the lower end. After the cannula is introduced the upper clamp is taken off, and when the tube has filled, the lower clamp is removed. After the needle is removed from the chest, a dry, sterilized dressing is applied and held in place by a plaster. At Bellevue Hospital sometimes cotton soaked in collodion is placed over the point of puncture. At all the hospitals the aspiration is usually continued until all the fluid that can be reached is removed; however there are certain conditions that may develop which call for suspention of the operation at once and removing the needle.

The following are recognized at all of the hospitals: (1) Any indication of cardiac embarrassment as indicated by the pulse, pallor, and dyspnœa. (2) severe pain; (3) persistent cough; (4) faintness.

The diet for a case of pleurisy with effusion adopted by the different hospitals is what is known as a soft diet: Eggs, gruel, soup, and, principally, milk. Dr. James at the Presbyterian Hospital keeps his patients on a "dry diet." At the New York Hospital milk is given exclusively as long as there is any fever. At Bellevue and New York hospitals one drug is given as a routine treatment in this condition, which is looked upon somewhat in the light of a specific, viz., syr. ferri iodide in 3 ℥ doses t.i.d. At Presbyterian and Roosevelt hospitals no drugs are given except stimulants, when indicated.

58 East Thirty-fourth Street.

EXTRAUTERINE PREGNANCY.*

By H J BOLDT, M.D.,
NEW YORK.

I shall limit myself in this paper to my personal experience, which consists of 258 cases seen by me in my own practice and consultation, since November, 1879, at which time I saw the first instance. (*American Journal of Obstetrics*, 1880, p. 502.) No instance is included in this number in which there was even an iota of doubt as to the correctness of the diagnosis. I exclude the retrouterine hæmatoceles on which I operated and which were not observed by me from the beginning of their formation. In the majority of instances I have had an opportunity to observe the diagnosis verified by operation, either by myself or my colleagues; and in a few instances it was verified by autopsy. Only twice was extrauterine pregnancy present, even its problematic existence not being diagnosed at all; both instances occurring in the beginning of my career. Several times ectopic gestation was diagnosed, but on operation another condition was found.

The causes of tubal gestation may be found in contortion of the tube; the presence of small neoplasms or mucous polypi within the tube, or of neoplasms in the wall of the tube; pathological changes in the fecundated ovum may also prevent it from migrating into the uterine cavity. Probably the most frequent cause is inflammatory conditions of the tube, which prevent tubal peristalsis. That the salpingitis in instances of tubal gestation is not due to the impregnation of the tube, but rather to an ascending infection from the uterus, may be assumed with certainty by the fact, so far as observed, that usually the most intense inflammation is present near the uterine extremity of the tube, diminishing in intensity toward the seat of impregnation. Further, that in those instances in which the non-impregnated tube was examined, a similar salpingitic process was present, corresponding in site and intensity to that of the impregnated tube.

According to the seat of the conception product, we may have various forms of extrauterine pregnancy; namely, (1) tubouterine; (2) interstitial; (3) proper (the most usual variety); (4) ampullar; (5) tuboovarian; (6) tuboabdominal; (7) ovarian. A tubouterine pregnancy may possibly become converted into a uterine pregnancy, if a few recorded observations are correct. After a tubal rupture, or a tubal abortion, we may, secondarily, have an intraligamentous, or an abdominal, pregnancy. Although it may appear to be a true abdominal pregnancy to the naked eye, yet the cases that have been submitted to microscopical examination by competent pathologists have been found to be primarily some form of tubal pregnancy. Ovarian pregnancy is still doubted by most authors, yet there have been such accurate descriptions of this variety, that its possibility seems beyond question. Some classify intramural pregnancy separately, but it is only a product of interstitial pregnancy, in which the ovum buries itself into the adjoining muscular structure of the uterus; an exceedingly rare variety of which I have seen but one instance.

Pathology.—The placenta forms at the site where the ovum is embedded, the maternal blood vessels coming from those of the tube. Much doubt has been expressed as to the formation of a decidua reflexa, yet while there is perhaps no complete formation recorded, there can be no question of its partial formations. Likewise many deny the formation of a decidua vera, whereas a decidua serotina has been recognized by most students of embryology. Regarding the existence of a decidua reflexa, the descriptions of Zedel, in the *Zeitschrift für Geburtshülfe und Gynäkologie*, 1893, p. 78 to 142, and those of Rosenfeld in the *Monatsschrift für Geburtshülfe und Gynäkologie* for September, 1901, as well as those of several other authors can, in my opinion, leave no doubt. The changes which are found in instances of salpingitis, are found in varying extent and intensity in nearly every instance. The changes which take place in the wall of the tube consist in an hypertrophy of the muscular structure and an increase of connective tissue. At and near the site of the ovum the muscular elements become atrophied by pressure of the growing ovum, and the proliferation of connective tissue. As a consequence we frequently find a thinning of the tubal wall at that point. Because of the additional weight of the tube, it has a tendency to sink to the pelvic floor, unless old adhesions prevent it from doing so. There it usually forms adhesions to the surrounding structures. An exception is: when the extrauterine pregnancy is of the true interstitial variety. In such patients the affected tube obviously does not descend. The swelling is in such instances so intimately connected with the uterus that it seems to form a part of it. The position of the uterine body assumes a more vertical line instead of the normal physiological anti-flexed position; it is also pushed somewhat out of the

*Read by invitation before the Richmond County Medical Society, October 8, 1902.

median line toward the unaffected side. It is, in fact, possible, if the examination is not carefully made, that the uterine swelling may be mistaken for the uterine fundus. In patients in whom the catarrhal inflammation is intense, the blood vessels increase in number and size with a thickening of their walls, the latter being most marked in the outer coat of the vessel.

Usually the death of the embryo within the tube takes place during the first two months after the faulty conception. Yet a few instances are on record in which the development went to, or nearly to, full term, and a living child was delivered by means of abdominal section. I have seen four instances of secondary abdominal and one of intraligamentous pregnancy at, or nearly at, full term.

The most frequent termination of tubal gestation is tubal abortion, to which Veit of Leyden first called attention, and not, as is believed by most physicians, a tubal rupture. Were the latter the case, the death rate from ectopic gestation would be greatly increased, because the intraperitoneal hemorrhage in instances of rupture is usually so large that, unless such patient is operated upon without delay, acute anæmia ends life. The exceptions to this rule are those patients in whom the process of rupture takes place slowly, then through a small partial rupture some blood exudes and forms a hæmatocele, which slowly becomes larger, and is gradually encapsulated. Another exception is, when the rupture takes place between the folds of the broad ligament, so that the bleeding has some check put upon it by the walls of that structure. The danger, even under such favorable circumstances, is not ended, because the surrounding walls of the hæmatocele may likewise rupture and the bleeding continue intraperitoneally. Even under the most favorable circumstances such patients may sometimes remain invalids for months. Besides the hæmatocele may undergo suppuration by infection with colon bacilli from its near relation to the intestinal tract, and thus become a pelvic abscess. In the most favorable instances the hæmatocele is gradually absorbed, but the adhesions which its walls necessarily undergo to the surrounding intestines and pelvic peritoneum, and pelvic contents, require a long time for their absorption; but they seldom remain permanent.

The most favorable instances of tubal abortion are those in which the conception product is aborted *in toto* within the first two or three weeks after conception. The bleeding is then usually moderate, and the blood and conception product is readily absorbed by the peritoneum. Later than the period mentioned, the abortion usually is only partial, and the bleeding continues with the formation of a hæmatocele, with a process progressing as already described.

The changes in the uterus accompanying ectopic gestation are similar to those of true uterine pregnancy, only in a less marked degree; in fact, I have seen a few patients in whom they were practically unrecognizable. The loss in consistency of the muscular structure was not even as pronounced as we usually find it in marked endometritis. The mammary changes are almost as constant as in uterine pregnancy. If my memory serve me right, I have seen but one or two patients from whom no cholostrum could be expressed from the breasts.

Symptoms.—We now come to the most important part to the general practitioner, namely, the objective and subjective symptoms. While for a patient the most important part is the proper treatment, the physician must necessarily make a correct diagnosis, and, as near as possible, be able to appreciate the conditions present before intelligent treatment can be begun.

Fortunately, the prolific discussion of ectopic gestation in medical literature during the last fifteen years, and the mastering of bimanual examination by most physicians, have placed the profession, as a whole, in a position to recognize extrauterine pregnancy in about 50 per cent. of the cases. This has been my experience in consultation practice during the last five years. The per centum mentioned in which correct diagnosis are made by family physicians becomes increased if the patient presents typical symptoms. Unfortunately, however, a goodly number of patients do not present the classical symptoms, so that even for a specialist the diagnosis may be difficult and sometimes only problematical.

The typical symptoms briefly mentioned are: The usual symptoms of pregnancy; non-appearance of menstruation at the expected period, when a patient has previously been regular. The delay of the period may be from a few days to five weeks or more. Usually, however, but one week or less elapses, and then other symptoms begin to manifest themselves. These consist of pain in the lower abdomen, most marked on the affected side. The pain is usually cramp-like and quite severe; it may continue for a variable period of time, usually not more than from half an hour to an hour. After the lapse of a day or two another attack of pain may follow, which may resemble the first attack, or it may be more severe. These paroxysms of pain may be repeated at varying intervals. Following or accompanying the first attack of pain, there usually is a loss of blood, which the patient generally thinks to be the menstrual flow, but it is tarry; that is, it has a dark appearance, and is thicker than normal menstrual blood.

The character and duration of the pain depends upon the process which is going on in the tube, there may be a tubal abortion, or a partial, or a complete tubal rupture in progress. I have never been able to notice a marked distinction in either the objective or the subjective symptoms between progressing tubal abortion and a gradual tubal rupture. In instances of sudden and complete tubal rupture, however, a patient experiences a pain so intense that she usually collapses; a condition due both to the pain and the large intraperitoneal hemorrhage.

The appearance of a patient who is having a gradual tubal rupture, or a slow tubal abortion, does not change markedly, because the loss of blood is comparatively small. The existing anæmia, of course, depends on the amount of blood lost. The uterus is often pushed somewhat to the opposite side, according to the size of the blood-mass. Intense pain in the rectum is sometimes complained of. In instances of complete rupture the appearance of the patient always indicates marked anæmia; the pulse may be absent or only faint, barely perceptible; the skin moist; in short, her appearance presents the picture of profuse hemorrhage. I have twice been able to open the abdomen under such circumstances without administering an anæsthetic, because of the existence of profound syncope.

With or soon following the first attack of pain in cases of progressing abortion or gradual tubal rupture, small pieces of membrane (decidua), sometimes one large piece, sac-like in shape, are expelled from the genital tract.

Bimanual examination will show the uterus somewhat enlarged and its consistency relaxed. To either side of the organ, and sometimes behind it,

if a hæmatocele is already in the process of formation, a mass, which is in close proximity to the uterus, is felt, which is very sensitive to the touch. The consistency of this blood-mass depends upon its age. The longer the hæmatocele exists, the firmer its consistency will be. The breasts usually contain cholostrum.

In cases of complete rupture, if the intraperitoneal hemorrhage has been as great as is usually the case, a careful examiner should be able to detect some fulness in the cul-de-sac of Douglas (free blood). Even if the patient is seen in a condition of syncope, pressure upon the abdomen usually shows that pain is caused thereby by the patient uttering a low groan, or moving as though to get away.

Patients without the prodromal symptoms of beginning rupture, or beginning tubal abortion, have never been seen by me, and it is my opinion that such instances are usually discovered accidentally, because if there are no symptoms present which cause a woman to consult a physician, how could the discovery be made, unless by mere accident. The symptoms of early pregnancy are present in such instances as well as in the other classes mentioned, including the swelling of the tube. A woman who is bleeding may suppose herself to be pregnant and undergoing an abortion, and this may really be the case, but it is essential to bear in mind the character of the pain. She may be pregnant intrauterine, and at the same time an ectopic pregnancy may also exist, this giving rise to the symptoms for which a physician is consulted. It is, therefore, necessary, bearing this possibility in mind, to make a careful examination of all such patients.

The symptoms vary quite often, so that there is no hard and fast rule for the existence of a definite line of symptoms. Menstruation, or at least what is supposed by the patient to be the regular flow, may be regular to the day, or it may be several days ahead of the regular time. The color of the blood may also vary. I have occasionally seen it as only a light pinkish discharge and in very small quantity. It may be an intermittent spotting, or a continuous flow (as is usually the case), or it may be present for two or three days, then cease, only to reappear a few days later. Bleeding from the uterus usually denotes the death of the embryo. Cholostrum may be absent.

There may be no appreciable change in the uterus at all. A number of times I have seen the organ practically normal; anteflexed, not relaxed in consistency, and of normal size.

The passing off of a decidua, upon which some writers lay so much stress, I have observed only in a small minority of patients.

There are many patients who do not present any marked symptoms at all, at least none which lead them to seek advice until sudden rupture with its concomitant effects set in. Frequently I have been called in consultation to see a woman in syncope under such conditions.

To recapitulate: The principal features upon which a diagnosis rest are: Arrested menstruation, generally but two or three days over time. A sudden attack of pain of a cramp-like character in the lower abdomen, located more especially to the affected side, associated at times with an intense pain in the rectum of a lancinating character. The blood passed is usually dark, grumous in appearance, and its flow is generally more or less constant. The paroxysms of pain continue for an hour or more, and are at intervals of from one to three days or more. Bimanual examination is painful, especially when the tumor to either side of the uterus is palpated. The uterus is changed in size and consistency, and is dislocated, according to the size and position of the blood-tumor. If the patient has not nursed a baby for more than two years, or has previously not been pregnant at all, the presence of cholostrum is an important symptom, especially when taken together with other existing symptoms.

Rupture is diagnosed by the suddeness of the attack and the excruciating pain followed by more or less pronounced syncope; and if it is possible to obtain a history from a relative, the data already given may aid in corroborating the suspected diagnosis.

The *differential diagnosis* is, at times, very difficult; in fact, it is impossible, in some instances, without an exploratory section. The condition in which it is likely to be impossible, is rupture of a large ovarian hæmatoma, especially if there is a continuance of oozing from the torn surface. Several such cases have been reported, and, in addition to the two already reported by me, I have seen one more.

It is likewise very difficult at times to make a differential diagnosis between subacute pysoalpinx, especially of gonorrhœal origin, and tubal pregnancy. I have made such mistakes two or three times, and many others have erred likewise, because, at times, the symptoms resemble those of our subject in every particular, so that one may be misled into making a wrong diagnosis, even though the uterine changes, nearly always accompanying ectopic gestation are absent. Usually in suppurative disease both tubes are effected simultaneously, whereas tubal pregnancy is but very seldom present in both tubes. But suppurative tubal disease may be, and frequently is, markedly present only on one side, the other side being but slightly affected. Vaginal puncture, or a small vaginal incision, would, of course, clear the doubt, but inasmuch as either condition requires surgical intervention to bring about a well-being of the patient, I do not see the necessity of making a preliminary vaginal section or puncture. The latter method has been in vogue many years for diagnostic purposes, but with better diagnostic ability of physicians during late years, it is not employed often. In results there is no difference between a puncture, as it should be made, and a small vaginal incision; in fact, for diagnostic purposes only, if one can not form a definite opinion, a puncture, properly made, is to be preferred, because the opening from the needle closes at once and leaves no scar in the vaginal vault. I very seldom have occasion to resort to it. Formerly curetting and examination of the scrapings was resorted to by many, and I thought it had gone entirely out of practice, but only recently I saw a patient upon whom this diagnostic method had been used. I can not find too strong terms of adverse criticism for such procedure, because a fecundated tube is liable to rupture extensively by the traumatism necessarily caused by such procedure.

Treatment.—The safest plan for the patient is to look upon every extrauterine pregnancy as one would regard a beginning malignant neoplasm, which, of course, should be removed as soon as possible after the diagnosis has been made; except under circumstances which will become apparent in the further discussion.

I shall dismiss the treatment by means of electricity, and that by the injection of morphia into the tubal sac, as well as the aspiration of liquor amnii, as measures which, in my opinion, are too hazardous, although there is sufficient evidence that these methods have, a number of times, been productive of good results in the hands of their respective advocates.

But two methods will be discussed by me; namely

the conservative and the surgical treatment. Preliminary to entering upon the consideration of either, I wish to lay stress upon the desirability of having such patients in a clinic (*i. e.* hospital or sanitarium). This especially holds good for those patients on whom it is intended to carry out a conservative plan of treatment.

If a patient is seen who has a tubal abortion in progress, and from the examination it is evident that the blood is well formed into a clot, determined by its consistency, it may be permissible to watch and wait, provided she is amid surroundings which will permit of immediate surgical intervention, if such becomes necessary. She should be kept absolutely at rest with a nurse in constant attendance; ice-bags, or, still better, an ice-coil applied to the abdomen; morphine to keep her comfortable, and fluid diet. She must, under no circumstances, be permitted to move in any way by her own exertion, either to change position, or at defecation, or urination. If, then, examination, repeated from time to time, shows that the size of the tumor does not increase markedly, and that its consistency does not become softer, but rather firmer, we are justified in the continuance of such treatment. The moment, however, that a severe attack of pain, with a rapid increase in the size of the blood-tumor, is present, operation is imperative for the greater safety of the patient.

If the history and symptoms show that the patient has had a complete tubal abortion, objectively determined by the absence of a thickened Fallopian tube, such as we would find were the embryo still within the tube, and if she has recovered from the shock thereof, a similar course is permissible. A hæmatocele will then form in the course of a few days to such an extent that it is readily recognized by the examining finger, and its increasing firmness and diminution in size would indicate that its absorption is progressing satisfactorily. I have observed twenty-three patients in the condition mentioned above, who went to complete recovery without surgical intervention. The first two of this number absolutely declined to be operated upon, and it was a matter of necessity to follow the expectant plan of treatment. A third patient declined operation and changed consultants; the new one at first made a different diagnosis, but a few days later he adopted the diagnosis previously made by me, the hæmatocele then having become distinct; but the patient again changed consultants, because consultant No. 2 strenuously insisted upon operation. The third consultant, I was told, made the diagnosis of pelvic cellulitis. No operation was performed, the patient finally recovering. There could not have been the slightest doubt as to the correctness of my diagnosis. Later I purposely followed the expectant plan of treatment in selected cases, and but twice was it necessary for me to subsequently perform an abdominal section among those so treated from the beginning of observation. On seven of that number a subsequent vaginal section was made to empty the hæmatocele. The rest made an uneventful recovery. The shortest time to complete recovery from the beginning of symptoms was four weeks, and in the longest it was a little more than three months before active household duties could be resumed. The average time was from five to six weeks. Before leaving the conservative treatment, I can but reiterate that if one is not fairly confident that a patient is likely to have an uneventful recovery, it would be safer to operate. But, as already remarked, there are patients who, under certain conditions, are equally sure to recover without surgical intervention. Experience has proved this to many. To show how important it is to appreciate the existing condition, I may mention that I have seen two patients within a year on whom I had made the diagnosis of ectopic gestation and for whom I advised immediate operation, because it was evident that the hemorrhage was progressing into the free peritoneal cavity, yet the family physician doubted the correctness of my diagnosis and wished to wait for further development. In one an opportunity was had to perform an autopsy three days later; in the other, six days later. In both it was thought that an error of diet had caused the colicky pains. My opinion had been requested in these instances as to the possible existence of appendicitis. They were both right tubal pregnancies with rupture.

Surgical Treatment.—But little need be said on this point. I invariably prefer to do an abdominal section on patients who have not a well-defined hæmatocele. Nearly simultaneously with Duehrssen, I conceived the operation of vaginal cœliotomy, and considered it of greater practicability. I did the operation about two weeks before I saw Duehrssen's first case reported in the *Centralblatt für Gynäkologie*, and have done several operations by that method, but have given it up again, because one has not as clear a field to work in, and it is no more time saving than the abdominal operation. On a patient who presents the symptoms of complete rupture of the tube, I prefer to operate at her home, if her general condition is such that it would endanger life to have her transported. The abdominal incision should be rapidly made, and be of sufficient length to permit one to work as expeditiously as possible. The blood sometimes wells up out of the abdomen as from a fountain. No attention should be paid to this. The pelvis must be reached at once, and the affected tube brought up and clamped. Then we should proceed to have warm saline solution poured into the abdomen by a nurse, while the operator removes the clotted blood from the pelvis and lower abdomen, and examines as to the condition of the other tube and ovary. The affected tube is then tied off, and the abdomen is closed in tiers. If the intraperitoneal hemorrhage has been profuse another assistant makes an intravenous infusion of from 1,000 to 2,000 c.c. of saline solution. No attempt is made to get all the blood out of the abdomen as long as the clots are removed, at least all that are easily accessible. The abdomen is left filled with saline solution. An operation for ruptured tubal gestation at an early period of gestation should seldom consume more than from ten to twenty minutes.

An important question is how to manage patients in whom the pregnancy has advanced to, or nearly to, the period of viability.

Some operators advocate immediate operation in all instances of extrauterine pregnancy as soon as possible after the diagnosis has been made without regard for the life of the child. Others prefer to wait for active placental circulation to cease, and then operate, with the hope of saving both mother and child.

While I have not had an opportunity to see a patient with a living extrauterine gestation product at or near the period of viability, I should, if an opportunity presented itself, advocate the latter procedure. The mother in such circumstances should be placed in a hospital or sanatorium, where she could be under constant competent observation, so that, should occasion arise for surgical intervention, it could be resorted to without unnecessary delay and without the dangers of transportation. The method of operating varies with different

operators. It is my opinion that no fast rule can be laid down which will govern all cases; each must be treated according to circumstance. As a rule, the most desirable method would be to extract the child, then to detach the placenta, and to stop hemorrhage by suturing the most profuse bleeding areas, and tightly tampon the cavity. The wall of the sac is to be sewn into the abdominal wound. The first packing may remain in the sac four or five days, but, subsequently, the dressings should be changed every other day, putting into the cavity less gauze and packing it looser until it has become entirely obliterated. The case is different if no sac is present at all. If it is possible to detach the placenta without causing too serious a hemorrhage, this course should be preferred. Unfortunately, the bleeding in such cases is likely to be so profuse as to endanger life directly, so that after making an attempt to remove the placenta, and it is not found practical to do so, the next best course would be to endeavor to isolate the placenta from the general peritoneal cavity by bringing the intestines and omentum around it, and to place the placenta near to the abdominal wound, to then pack into the cavity thus made a Miekulicz drain of sterile gauze. The subsequent treatment being similar to that described when the sac is attached to the abdominal wound. The danger from hemorrhage at a subsequent period, and from sapræmia, or sepsis in such instances, is obvious. Some operators advocate in patients in whom no sac is present, to close the abdominal wound and let Nature take care of the placenta. This is a good plan of treatment if one could be absolutely certain that every detail of the operation had been aseptic.

Patients with retrouterine hæmatocele should, if surgical intervention is indicated, be treated by making an extensive vaginal incision behind the cervix; the opening should be enlarged so that the operator can introduce his hand to clean out the coagulated blood and determine the interior condition of the hæmatocele, eventually to break up existing partitions. The cavity is then irrigated with sterile water and loosely, or tightly packed (according to the amount of surface bleeding), with sterile gauze. The dressings should be changed as often as circumstances may require.

ADHESIVE PLASTER STRAPPING FOR SPRAINS—THE INDICATIONS FOR ITS USE.

By FINLEY R. COOK, M.D.,
NEW YORK.

In the January number of the *New York Polyclinic*, 1893, Dr. Virgil P. Gibney published a paper on the subject of adhesive plaster strapping for spains of the ankle.

In the *New York Medical Journal* of February, 1895, he made another contribution, relating a series of cases which had been treated by this method with most gratifying results. He said that, as far as one could learn, this method was first employed by Mr. Edward Cotterell of London.

Strapping has been found to be serviceable in a great variety of articular and periarticular affections.

The pathological conditions which respond most readily to strapping seem to possess one factor in common, viz., relaxation of tissue.

The relaxation of tissues, following acute or subacute inflammatory disturbance, of a rheumatic, specific, gonorrhœal, tuberculous, or traumatic character. A relaxation of veins leads to a passive venous stasis, with exudation into joints, bursæ, tendon sheaths, and neighboring cellular tissue. Hence, we have swelling, tenderness, pain, and more or less impairment of joint function. We may, in addition, have redness and increased local heat, and in chronic affections, a cellular hyperplasia, leading to a connective tissue thickening of the normal structures within and without the joints, and the formation of adhesions.

To correct these conditions we usually employ counterirritants, such as hot fomentations, alternating hot and cold douches, stimulating lotions, baking, blistering, and the Paquelin cautery. We employ active and passive motion, pressure, massage, variable immobilization, and gradually diminishing support and protection.

The good results obtained in strapping, when these indications are present, especially in sprains and contusions and stiffened joints following prolonged and over-immobilization, are due to the fact that adhesive plaster strapping, when properly applied, meets, in a measure, many or all of those indications.

In the first place, strapping affords support. It can be applied so as to act as a perfect substitute for sprained ligaments, relieving them from all superincumbent weight, which adequately accounts for the ease with which patients walk about.

In order to secure the full amount of substitution, the ordinary diagnosis of sprain is inadequate.

It is not only necessary to determine what particular ligament or ligaments are involved, but, in addition, when a ligament has more than one insertion, or more than one function—as in the case of the external and internal lateral ligaments of the ankle-joint, each having three distinct fasciculi—to ascertain what special fasciculus or fasciculi have become the seat of sprain.

Such a diagnosis is, in most cases, readily made, by ascertaining the position of the parts when subject to trauma, the position of the parts at rest and in motion following trauma, by outlining the area of maximum tenderness and maximum local heat, and by comparing the amount of pain induced by forcing the parts into all the extremes of motion, of which the joint is capable.

For illustration, the ankle turns in a position of equino-varus, straining the anterior fasciculus of the external lateral ligaments. The foot will be held in a moderate position of calcaneo-valgus, thus affording the greatest comfort and relaxation. A limited area of maximum tenderness and maximum surface heat will be found to extend over this fasciculus; from its origin at the inferior margin of the external malleolus, downward and forward over its insertion to the astragalus.

The forced position of calcaneo-valgus is the *least* painful of all, and may be comfortable; pain increases in the order of calcaneo-varus, equino-valgus, equinus, and equino-varus, the latter, the original position, the most painful of all.

The ankle is strapped in the position of moderate calcaneo-valgus. In the second place, strapping affords protection. In the third place, strapping induces counterirritation; more effective following the use of the Paquelin cautery and more effective still when, by reinforced strapping, the underlying strips are forced into folds. The amount of counter-irritation varies with individual susceptibility. In one case a severe dermatitis, with great swelling of the arm, ensued in three days after strapping for a sprain of the biceps. It depends, also, on the variety of plaster strapping employed. In the fourth place, fomentation. After the removal of strapping the parts are seen to be moist, bleached, and softened. In the fifth place, strapping affords pressure. It

supports relaxed blood vessels, and is the most effective means of limiting swelling. Pressure is increased through reinforcement. Lastly, strapping with the use of the parts is an excellent form of massage. We believe this to be the most important function of strapping. In former days manual massage was the most effective treatment for sprains, and the success of osteopathy is attributable to its use.

The following case demonstrates this action of strapping:

Mary F. had been confined to her bed for six weeks with an ulcer of the foot, resulting from a burn. Various ointments and lotions were ineffective. The foot was swollen to nearly twice its normal proportions. Over the dorsal aspect there was an indolent ulcer, the size of a hen's egg, one-half inch deep throughout, the floor of which was the seat of a thick slough. There were absolutely no signs that the slightest healing had taken place during the six weeks' confinement to bed. The foot was immediately strapped from the toes well up above the ankle. She got up and went about her work as usual. Two days later, when the strapping was removed, the change was most astounding. There was only a trace of swelling and the slough came away with the strapping, leaving an active granulating surface exposed. Healing was rapid, after successive strappings, and was complete in twenty-one days. Pressure or support could not have brought about such a result, neither could strapping and rest. It was undoubtedly the action of the various tendons and muscles about the foot, beneath the strapping, which caused the rapid disappearance of the swelling.

Discrimination should be made between sprains and contusions. In contusion, the affected side is relaxed; in sprains, is placed on a tension.

In contusions swelling is apt to be more marked, and in position, more independent of joint structures; in sprains, less in extent, and in the early stages will bear a relation to special structures about the joint. In contusions superficial pain and tenderness are more characteristic; in sprains deep pain and tenderness are more marked. In contusions redness and heat are more confined to the area of swelling; in sprains redness and heat, in the early stages, overlie distinct tendons or ligaments in the neighborhood of joints. In contusions ecchymosis is early in appearance and more constant; in sprains, later and less constant.

The method of treatment is different. In contusions the parts are strapped, relaxed; in sprains, in closer approximation. Cases in which contusions and sprains are concomitant are very common. The signs are mixed, and those either of one or the other will predominate, the treatment varying accordingly.

The writer has employed strapping for the past seven years, and the following cases are illustrative:

Case I.—Patient, Mary S., was admitted to the P. H. Hospital in the fall of 1895. Six months previously she had sustained a Potts' fracture of the right side, which had been encased in plaster-of-Paris six weeks. For six months she had used crutches, and could not bear her full weight on the affected side. The ankle was only slightly swollen. Localized tenderness over the anterior and middle fasciculi of the internal lateral ligaments. The foot was held in a position of valgus, probably as a result of the fracture, and this position being unfavorable, might account for the stubborn nature of the sprain. Motions were limited. The ankle was strapped, and she was urged to walk about, which she did with no pain, but with great apprehension. In four days she was walking freely about the ward, without pain, limp, or crutches. The ankle was strapped in varus.

Case II.—In October, 1898, a young girl came to the Vanderbilt Clinic with a lame knee, which had been immobilized for two years in a plaster cast. It had been regarded as tuberculous. The joint was slightly swollen, ankylosis nearly complete, only 5° of motion. Only moderate atrophy of thigh and calf existed. A diagnosis of over-immobilization in a rheumatic arthritis was made. The treatment was active and passive motion, and the Paquelin cautery followed by strapping. In four months the patient had recovered the full amount of motion, and walked and ran without pain or limp.

Case III.—In July, 1902, a young lady at Garrisons, was thrown from a high trap, spraining her ankle. That same evening she was to have her coming-out ball. Looking forward to the rôle of a wall-flower was not particularly entrancing. The ankle was swollen, tender, and painful. Strapping was applied a few hours after the accident. In a few moments she was walking about freely without pain or limping. She danced eleven turns that night, and considered herself cured the next morning. On the third day, when the ankle was restrapped, very slight tenderness and swelling remained. Since then she has never had any further trouble.

Case IV.—Last winter Madam S., weighing over 220 pounds, turned her ankle on the pavement, and not being able to stand or walk, was taken home in a carriage. The next morning the ankle was swollen, red, and painful. She hopped about the house with great distress. Ambitious and eager to keep up her work of expert hair dressing, which required walking several miles a day in going from house to house, the ankle was strapped, and she was told to go about as if nothing had happened. This she did, and five days later, when the strapping was removed, it was not deemed necessary to pursue further treatment.

Case V.—In July a young man applied for treatment, who, seven months before, had wrenched his left knee, since when he had walked with pain and limp. He had been advised to undergo an operation for a loose cartilage. Upon examination, the knee-joint was swollen, patella floating, increased localized heat and tenderness over the internal lateral ligament. Extension normal. Extreme flexion painful. Adduction negative, abduction painful. No loose body was found. Strapping afforded immediate relief. Treatment was continued for five weeks, at the end of which time, he could walk or climb without support, and without pain or limping. Slight thickening about the joint remained.

In this case the Paquelin cautery was used before the strapping was applied.

Case VI.—On December 1, 1901, a professional pitcher was placed under my care with a lame shoulder. Two years prior to this time he had sustained a severe wrench, and since then he had not been able to throw a ball. There was slight swelling, and thickening about the upper aspect of the joint. Adduction and abduction somewhat limited and painful. External rotation limited. Internal rotation, flexion, and extension negative. Also tenderness over the upper aspect.

A diagnosis of sprain of the superior fibers of the capsular ligament was made, and strapping applied accordingly. One month later he could throw a ball with the shoulder strapped, but not otherwise. In six months he played a professional game without any support whatever, when strapping was discontinued.

Case VII.—The following case shows a comparison of different treatments. October 16, 1901, Mrs. K. came to the Vanderbilt Clinic with a severe

sprain of the external lateral ligament, associated with marked contusion. The foot and ankle were very much swollen. She walked with great pain. A wet lead and opium dressing was applied, and she was instructed to remain in bed and keep the dressing wet. On the third day she returned, and the swelling had increased in a surprising manner, now extending to the upper third of the calf. Function was more restricted, and pain in a like manner, considerably worse. Strapping was now applied, and after walking several laps around the room, she walked home, a distance of over a mile. Three days later she paid a second visit to the clinic, without pain or limping, and the swelling had subsided in the most remarkable manner. The ankle was restrapped, and she did not return for further treatment.

5 Park Avenue.

INGUINO-SUPERFICIAL HERNIA (KUESTER).*

By ALEXIS V. MOSCHCOWITZ, M.D.,
NEW YORK.
ADJUNCT ATTENDING SURGEON MOUNT SINAI HOSPITAL.

Ever since the introduction of antisepsis into surgery, operations for the cure of inguinal hernia have become of such frequent occurrence that there is given abundant opportunity for the observation of anomalies in the location of the hernial sac. Even before the advent of this epoch however, observers (Boyer, Bartholin) mention in their writings cases in which the hernia did not descend into the scrotum, but spread out between the layers of the abdominal wall. Kroenlein and Kuester, however, deserve the credit not only of having called attention to two distinct abnormalities in hernia, but of having described them in such detail and with such accuracy that, with the exception of adding case reports, nothing further remains to be written.

Undoubtedly the most complete and the most comprehensive article on interstitial hernia, as a whole, has been written by Goebel.[1] At the very outset, I beg your indulgence to quote two sentences from this exhaustive article, as in a measure they invite publications of this nature, and furthermore they form a justification for the publication of the solitary case which it has been my good fortune to observe and operate upon. Goebel collected all the published cases of interstitial hernia, and in spite of the appreciable number thus collected, has this to say in his introductory remarks: "Leaving out of consideration the sparse reports of German authors on this abnormality, the cases of this form of inguinal hernia offer sufficient of interest to merit publication, when an operation has exposed the anatomical relationship of the parts;" and, further on, in speaking of that particular variety which is usually designated as "inguino-superficial hernia," he says that "it has been very rarely observed." In view of these facts, the publication of my case has been decided upon:

Harris S., twenty-eight years of age, was admitted to the Mount Sinai Hospital in the evening of March 5, 1902. As far back as his recollection goes, the patient has had only the right testicle in the scrotum. Since adolescence he has noticed a small ovoid swelling in the left inguinal region, which he has looked upon as the missing testicle. When twenty-one years of age, the patient noticed in this testicle a tendency to descend, and, as a matter of fact, the positive assertion is voluntarily elicited from him, that the testicle has descended to the root of the scrotum, at least one and one-half inches. This gradual descent was accompanied by considerable pain in the inguinal region, which, however, the patient learned to alleviate by pushing the testicle back to its original position. This condition continued for approximately three years, but the accident occurring with greater frequency and increased pain, he was forced to seek advice at a local dispensary. He was advised there to wear a truss in such a manner that the pad was to lie on a plane above the testis. The patient tried to follow these instructions for a while, but the pain was so unendurable that he was forced to abandon the attempt. During this time, however, he noticed that he obtained relief only when the testis accidentally slipped upward, so as to lie above the pad of the truss. The natural outcome was that he soon learned to reverse the directions given to him, and for the past seven years he has worn the truss in such a manner, as to prevent the descent of the testis toward the scrotum. In spite of all precautions, the testis occasionally slipped below the pad, and this was always accompanied by very sharp pains, relief from which occurred only when the testis was returned to its abnormal position.

Twenty-six hours prior to admission, while walking down stairs rather hastily, the patient suddenly felt a very sharp pain in the left inguinal region; this was accompanied by nausea, and only with the exertion of a great deal of will-power was he able to walk to his home, some three blocks distant. On arriving at his home he again attempted to obtain relief in his usual manner, by pushing the testicle upward. Somewhat to his surprise, however, the mass was immovably fixed in its position, and no amount of manipulation would move it thence; a further point which struck the patient at once was the fact, that the mass was at least double its former size. He remained in this condition until the following morning, when his family physician was called, who, recognizing the serious condition, advised his removal to the hospital.

He was admitted to the hospital just twenty-four hours after the accident, and the following condition was found: In the left inguinal region, parallel with and above Poupart's ligament, there was to be seen and felt a smooth, ovoid, painful, and tender mass, about the size of a goose-egg. It was firmly fixed to the deep structures, but the skin covering it could be moved slightly in all directions. On careful palpation this mass could be differentiated into two unequal superposed halves. The inferior and, at the same time, anterior half was smaller, firmer to the touch, and distinctly more tender; the superior and posterior half was larger, but less tender, and imparted to the examiner an indistinct sense of fluctuation.

The external inguinal ring could not be palpated; the left half of the scrotal sac was empty. There were no abnormalities on the right side. The bowels were constipated, but there was no tympanites, and no symptoms referable to the peritoneum were noted.

The diagnosis of torsion of the spermatic cord was made, and immediate operation was proceeded with. An incision was made over the prominence of the inguinal mass, along its entire anterior surface, and parallel with Poupart's ligament. After the skin and superficial fascia had been divided and retracted the mass was exposed in its entirety. (Fig. 1 and Fig. 2.) The mass previously described, of a deep bluish-black color, presented in the wound, and in addition there was to be seen, emerging from its inferior and mesial extremity, a flat cordlike

*Read before the Surgical Section of the New York Academy of Medicine, November 10, 1902.

structure, extending downward and inward, which was recognized as the spermatic cord. On reaching the upper margin of the external inguinal ring, this was bent acutely upon itself, and entered the inguinal canal. No torsion or twisting was to be seen. The previous diagnosis was therefore abandoned, and in its place that of strangulation of the testicle was made; the testicle being dislocated upward and outward upon the aponeurosis of the external oblique, to which it was slightly adherent. It was also seen that the tumor did not consist

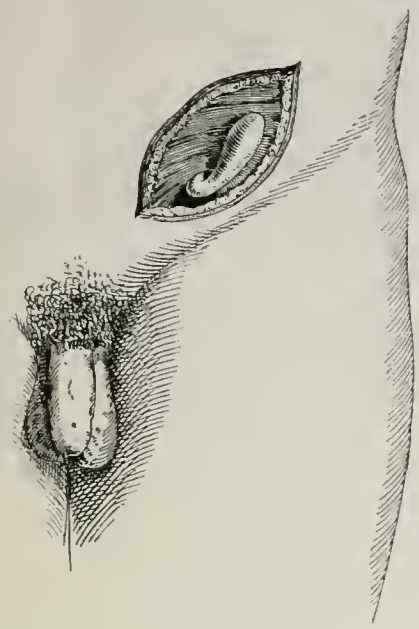

FIG. I.—Appearance of the Tumor after Division of the Skin and Superficial Fascia.

entirely of testicle, as there was in connection with and posterior to it a separate definable mass, which for the time being was taken to be an inflammatory hydrocele.

When the whole mass was freed from its attachments and elevated so that its direction was in a line with the inguinal canal, it suddenly and visibly became smaller, from reduction of its contents. The sac which had originally been situated posteriorly to the testicle, but on account of the replacing of the testicle into the normal position, had now come to lie anteriorly to it, was opened; this gave escape to a slightly sanguinolent, odorless, transudate, "hernia-water." A large mass of omentum was seen occupying the deeper portion of the sac, which was reduced with very little difficulty; the testicle, of a deeply-purplish color, lay within the sac; in other words, we had to deal with a hernia of the so-called congenital variety.

After a tunica vaginalis had been formed from the most inferior portion of the sac, there followed the usual steps of the Bassini operation, with the following additional steps, that the left half of the scrotum had to be dilated for the reception of the testicle, and that in suturing the aponeurosis of the external oblique, each stitch was also made to take in a small bit of the cord, in order to prevent, if possible, another dislocation of the testicle; to assist further in this attempt, the scrotal opening was also narrowed by suturing, leaving just space enough to transmit the cord without undue constriction.

There was some pain in the wound on the second and third days, necessitating an inspection, but nothing abnormal was found. Primary union resulted, and the patient was discharged cured on the sixteenth day.

Examination of the patient eight months after the operation shows that there is no recurrence of the hernia, that the testicle is practically of normal size, and that it is still down in the scrotum; in other words, it is practically normal, with the exception that it is very slightly softer than its fellow.

If the history and operative findings of the case just reported are carefully looked into, the following conclusions must be arrived at: Originally the man undoubtedly had an undescended testicle, with an open funicular process. At the period of adolescence, in consequence of the increase in manual labor, which this age entails, the testicle was gradually forced out of the inguinal canal. When it had been entirely extruded through the external ring, it found the entrance to the scrotum barred; these factors caused so much pain that the patient, in attempting to relieve himself, soon found that he could do so by pushing the testis upward. However, instead of pushing it back to the position it occupied before, he pushed it upward and outward, so that the testicle came to lie between the skin and superficial fascia on one side, and the aponeurosis of the external oblique on the other. This gave rise to the rare, if not unique, anomaly, that the testicle lay dislocated in the position above described, with an open funicular process behind it; both the spermatic cord and the funicular process were bent sharply upon themselves at the upper margin of the external inguinal ring; but so long as there was ample room at the ring for these structures to pass through, there did not arise any acute symptoms; whether the intracanalicular portion of the funicular process had any hernial contents or not is merely speculative, and in fact of no great moment. While the patient was running downstairs on March 7, in all probability the intraabdominal contents found their way into the open funicular process; not only into that portion lying within the inguinal canal, but also into that which lay reflected upon the

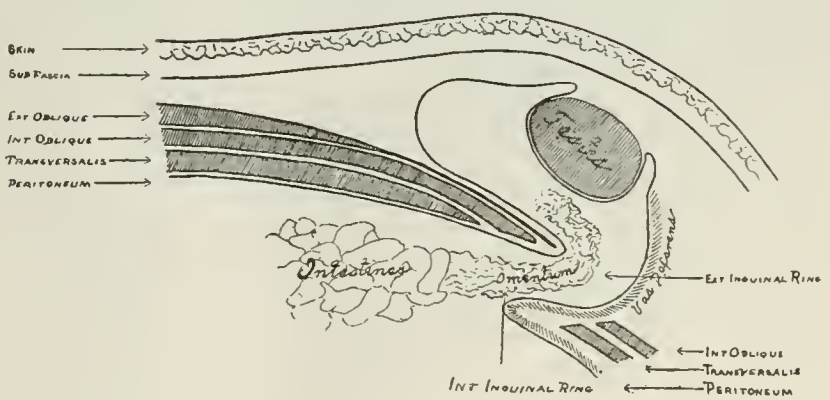

FIG. II.—Diagrammatic Cross-section of Hernia, Passing Obliquely through the Inguinal Canal.

aponeurosis of the external oblique. From the anatomical relations of the parts, it is very readily seen that under these conditions the following accidents must have supervened:

1. An acute flexion at the external ring of whatever hernial contents had passed it, followed by an interference with the circulation, accompanied by the phenomena dependent upon this condition.

2. Because of the increased contents of the funicular process where this structure was bent, undue

compression was brought to bear on the reflected portion of the spermatic cord, which caused an interference with the circulation of the blood to and from the dislocated testicle.

3. The absence of more violent symptoms is to be accounted for by the fact that omentum only, and not intestines were strangulated.

4. A cure could result only by operation, or, if a diagnosis had been feasible, by a reduction of the hernial contents. It is needless to say that taxis could be performed only in a direction first downward and inward, then upward and outward.

As already stated in the introductory remarks, this particular variety of abnormal localization of the hernial sac is exceedingly rare. The few cases recorded, however, are described so minutely in all details, that in order to avoid repetition, I can do no better than to refer those interested to the classical article of Kuester[2] upon this subject.

It will be sufficient if I note here that all of the remarks to follow are applicable to that particular subvariety of interstitial hernia which has received the name of inguino-superficial hernia. As is well known, this is the form in which the hernial sac is spread out between the aponeurosis of the external oblique and the integument covering it.

In 1900 Goebel (*loc.cit.*) gave a masterful description of the different varieties of abnormalities (hernia inguino-properitonealis, interstitialis, and inguino-superficialis), and collected all of the cases published up to that time. Of the inguino-superficial variety he collected in all fourteen cases, viz.: Kuester,[2] three cases; Fano,[3] one case; Curling,[4] one case; Hulke,[5] one case; Moynihan,[6] one case; v. Wahl[7], one case; Macready,[8] six cases; Undoubtedly there are other cases; the actual number cannot be stated, as some writers, *e. g.* Langton,[9] merely give a description of this variety of hernia, and do not state the number treated, nor do they give any histories. Since then Goebel[10] has published another characteristic case and described it in full detail.

In addition to the above, I have been able to find one other case in literature, which is so concise in its description that it may serve as a type for all. Possibly on account of the rarity of the journal in which it was published, and possibly also because of the title, which does not give an accurate idea regarding the true nature of the case, it has escaped all writers until now. The case is the following:

Salzman[11] found a hernia at the autopsy of a patient who had died of pleurisy. The hernia, of the so-called congenital variety, was exceedingly large, containing approximately one-half of the intestines, extended from the left inguinal region upward and outward to the ribs, and was situated between the skin and superficial fascia on one side, and the external oblique on the other. The opening through which the hernia made its exit from the abdomen was a round hole about the size of a dollar, and was situated about one inch above the inner third of Poupart's ligament. On account of the long duration of the hernia, the inguinal canal was absent, and in its stead only the ring above described existed. The testicle, atrophied to one quarter of its normal size, was found to lie within the hernial sac, at about the level of the anterior superior spine of the ilium.

In spite of this relatively small number of cases recorded (I have been able to find but seventeen, including my own), one might say that the subject of this variety of hernia is well studied and understood in all its details. Only one point is still under discussion, and that is the genesis. In other words, why do some herniæ, instead of taking the usual course in the direction of the scrotum, take this unusual course, and spread out between the layers of the abdominal parietes; in our case, between the superficial coverings and the aponeurosis of the external oblique?

It would exceed by far the intended limits of this paper were I to recount all the theories which have been proposed with the idea of accurately explaining the occurrence of this abnormality.

Primarily, the most characteristic point of all forms of interstitial herniæ (this term is used here in the collective sense) is their association with some form and degree of cryptorchism. It would however, be manifestly wrong to build an absolute hypothesis on this point alone; while it is true, that practically all interstitial herniæ are associated with some degree of cryptorchism, the obverse does not hold true, for all cases of cryptorchism are not associated with some form of interstitial hernia. As a matter of fact, we are now in possession of a goodly number of convincing statistics. Macready (*loc. cit.*) has found in the statistics of the London Truss Society 158 cases of cryptorchism in 17,538 patients afflicted with hernia; but of these 158 cases, only fifteen, or about 10 per cent., were of the interstitial variety. While, of course, by no means absolutely convincing, it is still a matter for good argument that cryptorchism alone and uncomplicated, *i. e.* without any additional factors, gives rise only very rarely to an interstitial hernia. My personal experience is too limited to discuss the genesis of all forms of interstitial herniæ; for the present only the inguino-superficial form interests us, and for this form the following method of genesis appears to be not only possible, but also most probable. It certainly was the method in the case above described in detail; and I am sure if the history is carefully weighed it will not require further or more convincing argument. I might add here that my patient was possessed of more than the ordinary intelligence, that he related his history in a straightforward manner, and that I did not at any time put any leading questions to him.

Originally we evidently had to deal with the following two factors: (1) A cryptorchism; (2) An open processus vaginalis.

In the course of time, it is not only possible, but even probable that the hernial contents, let us say omentum or intestines, found their way into the open processus vaginalis. Owing to the increased intra-abdominal pressure, the testicle gradually, but surely dilated the external inguinal ring, and in this way it attained a certain degree of mobility, slipping in and out of the inguinal canal. The next step in the development was the extrusion of the testis entirely out of the ring; owing to the shortness of the cord, so much pain was produced that the patient, in order to alleviate this pain, attempted to slip the testis back into the inguinal canal, but instead of doing this, he slid the testis between the skin and the aponeurosis of the external oblique, and in doing so, the structures of the cord necessarily were bent. It must be remembered, however, that in this case we had to deal not only with the usual structures of the cord, but in addition with the open processus vaginalis. Because of the flexion above described, that portion of the processus vaginalis, distal to the external inguinal ring, was empty. When on March 8 the accident above noted occurred, either because of greatly increased intraabdominal pressure, or because of the momentary favorable position of the sac, the hernial contents found their way into the extra-inguinal part of the processus vaginalis. But it was just as difficult for the hernial contents to become reduced as it was for them to find their way into the

sac. The final step was that of congestion, swelling, etc., as we usually find it in a strangulated hernia.

I have gone at some length into the explanation of this point, perhaps longer than warrantable. While I lack the objective proof, I am firmly convinced of the correctness of my view. Perhaps it will aid in clearing up the genesis of other cases.

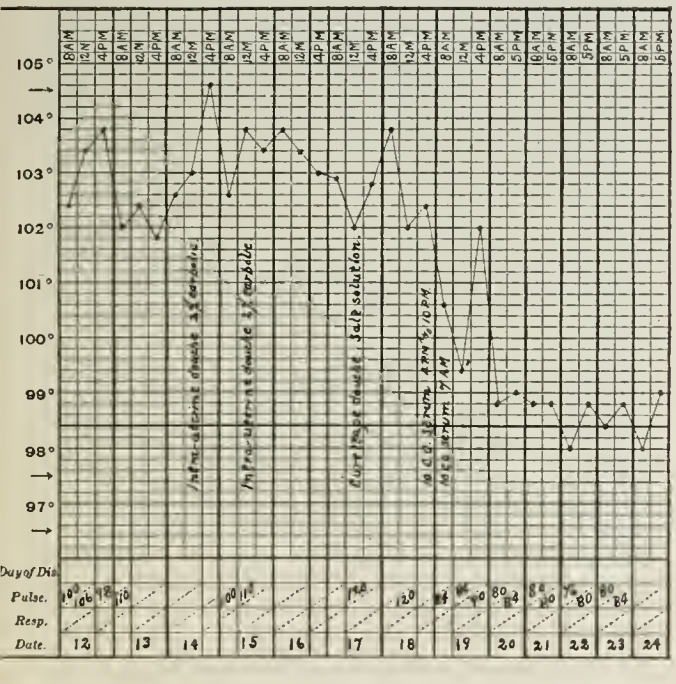
925 MADISON AVENUE.

REMARKS ON BACTERIOLOGY AND SERUM TREATMENT OF PUERPERAL SEPTICÆMIA, WITH AN ILLUSTRATIVE CASE.

BY CHARLES S. WHITE, M.D.,
WASHINGTON, D. C.
ASSISTANT DEMONSTRATOR IN PATHOLOGY IN COLUMBIAN UNIVERSITY MEDICAL COLLEGE; GYNECOLOGIST IN DISPENSARY OF COLUMBIA HOSPITAL AND UNIVERSITY HOSPITAL (COLUMBIAN).

WHILE the subject of the treatment of puerperal sepsis is a trite one, there is probably no other disease which gives the physician greater concern or more anxiety, be he a general practitioner or a skilled obstetrician. The advent of antisepsis and asepsis



has undoubtedly diminished the prevalence and mortality of infectious fevers, but we feel relieved when all dangers of post-partum fever vanish. Strive as we may to prevent it, cases do occur, not through negligence of the accoucheur or nurse, but probably through an invading army which lies dormant in the vagina until a suitable nidus presents itself for infection. We know that pyogenic organisms, probably in an attenuated form, frequently exist in the vagina and uterus of the lying-in patient, and these are just those cases in which no possible source of sepsis can be ascertained.

The methods of combating puerperal septicæmia have been legion, and vary from "masterly inactivity" to hysterectomy, the advocates of each particular line of therapy or surgery stanchly defending and recommending his respective plan.

The case reported below simply adds its mite to the evidence in favor of the serum treatment, but will not serve as an infallible therapeutic guide in future cases. However, our convictions are but mosaics, and it requires many small pieces of clear-cut truth, cemented by the mortar of reflection, to mold a concrete opinion.

Mrs. S., thirty-one years old, VI Para. Good family history and labors normal. On April 6, 1902, after a short, normal labor, she gave birth to her seventh child, a vigorous baby, and for the following six days her puerperium was featureless, with the exception that she felt stronger than after previous deliveries. On April 12 her temperature became elevated for the first time, reaching 102.2°, accompanied by chilliness and malaise. The fundus of the uterus was then about three inches above the pubes, but this organ was not the site of pain or offensive discharge, though the lochia was blood-tinged. The following day she was not so well, and complained of intense headache and sleeplessness. The temperature remained above 101.8°. Her diet was restricted, the infant taken from the breast, and sedatives and hypnotics given with disappointing results. She did not improve on the 14th, but grew worse; the thermometer recorded 104.6° at 4 P.M. An intrauterine douche of 2 per cent. carbolic acid solution was given, and a daily vaginal douche of boric acid was ordered. The flushing of the uterus was repeated on the 15th. Her prominent symptoms at this time were anorexia, coated tongue, and heavy breath, constipation, abdominal distention and tenderness, rapid (110 to 120), small pulse, violent headache, and persistent insomnia. Whiskey and strychnine were freely used, as on the day previous. She was evidently growing worse from day to day.

Dr. Gott of Falls Church, Va., asked me to see the patient April 17. She presented a striking picture of septicæmia, with sallow skin, sunken eyes, abdominal tenderness, pulse of 120 and evident exhaustion. She was placed across the bed, a culture was taken, and the uterus was gently curetted with a dull instrument (without anæsthesia, as it seemed contraindicated), removing some débris but no placental tissue, then the uterus was cleansed with normal salt solution. The depth of the uterus was seven inches. Vaginal douches of 7 per cent. solution of sodium chloride were to be given night and morning and the stimulation increased. She was fairly comfortable the same evening, and succeeded in getting some sleep, but awoke early next morning feeling as badly as before. Her temperature at 8 A.M. was 103.8°. The culture was examined and found to contain the streptococcus pyogenes and a short bacillus. (Dr. James Carroll, U.S.A., kindly verified my findings.) The urine was free from albumin, sugar, and casts, though it had shown sugar during the early part of the pregnancy.

I saw her again on the 18th. Her condition seemed unchanged, and I ordered 10 c.c. of anti-streptococcic serum every six hours until 30 c.c. were given. The first dose was given at 4 P.M. the same day; the second at 10 P.M., and the third at 7 A.M. on the morning of the 19th. It was not given as

specified, as she was enjoying her first refreshing sleep for several days at the time the third dose was due. Within twenty-four hours after the serum treatment an urticaria appeared, remained about six hours with itching, then melted away. On the morning of April 19, at 8 A.M., her pulse was 84, temperature 100.6°. At 4 P.M. her temperature rose to 102°, but the pulse was but 90. The following day (20th), at 8 A.M., pulse was 80, temperature 98.8°, and subsequently her temperature never exceeded 99°. Dr. Gott informed me a month later that her convalescence was not rapid, but was entirely satisfactory and free from sequelæ.

I would call especial attention to the diminished pulse rate following the use of the serum. Unfortunately a record of the pulse was not kept previous to my visit, but it varied from 98 to 120. The fall in temperature and improvement in the mental symptoms and general aspect is significant. I attributed the change entirely to the serum, and consider that it demonstrated its specific action in this instance quite as markedly as antitoxin in cases of diphtheria. That the patient made a smooth, satisfactory recovery, free from relapse, is further evidence of its neutralizing properties.

Without discussing the *pro* and *con* of serum therapy it is apropos to say that Marmorek claims that anti-streptococcus serum is suitable for all cases of streptococcus poisoning, while the consensus of opinion rather inclines to the belief that it is potent in certain forms only of streptococcic intoxication, and, inasmuch as we are unable to differentiate this specific infection, I believe we are justified in employing it in all sepsis due to this organism. Dangerous or alarming symptoms following its use never or rarely occur, and, while it may fail in some instances, it is not disappointing, on the whole, but, on the contrary, remarkable achievements are recorded. In several instances in which I have used it the patient was unimproved, but in these cases the streptococcus was not found, but the serum used as a last resource.

The use of serum is not new, and that it has not proved to be a specific for streptococcus pyogenes is not an argument against its use. We have but a few examples of the specific action of a drug in the whole range of medicine, notwithstanding the abundance of literature to the contrary. On the other hand, the ultimate results will be gratifying and even brilliant in well-chosen cases. By this latter term I mean cases of streptococcus infection, excluding all processes due to the other pyogenic organisms, possibly excluding erysipelas. In this connection, the work of Moser of Vienna with scarlatinal streptococcus serum is especially promising, having reduced the death rate from 13.09 to 8.99, in spite of the fact that he admitted only the severe cases to St. Anna Hospital for this treatment.

The Blood During Pregnancy, Parturition, and the Puerperium.—William Sengel analyzes the results of former investigators, and gives a bibliography, and the tabulated results of his own studies in twelve primiparæ, twenty-five multiparæ, two of the children, and of a differential count in fifteen cases. He concludes: (1) During the first three months of pregnancy there is frequently anæmia, but no hyperleucocytosis; (2) The blood during the remainder of pregnancy is usually characterized by increase in the number of red blood-corpuscles, in hæmoglobin content and in leucocytes, the last being especially increased in primiparæ; (3) A greatly-increased leucocytosis occurs during parturition, being greater among primiparæ; (4) The hyperleucocytosis rapidly diminishes after labor, showing a slight rise about the fifth or seventh day and again about the eleventh day; (5) This hyperleucocytosis is due to the polynuclear neutrophiles; (6) During the first ten days of the puerperium there is usually a diminished number of red blood-corpuscles and of hæmoglobin content; (7) There is often a polycythæmia after the second week of the puerperium; (8) Hyperleucocytosis disappears in normal cases by the fifteenth day; and (9) Simple mastitis, suppurative mastitis, postpartum hemorrhage, and frequently puerperal sepsis, cause a marked hyperleucocytosis above that already existing. —*Yale Medical Journal.*

The Utility of Lumbar Puncture in the Diagnosis of General Paralysis.—A. Joffroy and E. Mercier, from the results of their study of the subject, state that lymphocytosis is very rare in occurrence in chronic alcoholism with meningitis; nothing points toward its existence in the early stages of alcoholic intoxication. When the quantity of white blood-corpuscles is not augmented, one is justified in rejecting the supposition of the existence of general paralysis; if, on the contrary, the quantity is above the normal, and if no other affection of the nervous system exists to explain this presence, one is justified in diagnosing general paralysis. The authors cite a case in which the presence of general paralysis could only be suspected; a lumbar puncture with examination of the cerebrospinal fluid showed that the number of white blood-corpuscles was augmented. A positive diagnosis of general paralysis was made, which was fully justified by subsequent events. An examination of the cerebrospinal fluid will help to decide between general paralysis and an attack of mania or of melancholia; also between paralysis and mental confusion.—*The Journal of Menta Pathology.*

A Case of Pathological Sleep in an Hysterical Subject.—Serge Soukhanoff describes the case of a markedly hysterical young woman, who after having for some time exhibited symptoms of sleepiness, which gradually encroached more and more upon the waking hours, finally fell into a profound sleep. Four days after she had been thus sleeping, she was seen by the author. The sleep lasted three days longer, but she would occasionally awake enough to get out of bed and drink water. Several other attacks of prolonged sleep followed, alternating with hysterical attacks. From an analysis of the case the author concludes that the pathological sleep here considered has two morbid elements: Firstly, the patient unconsciously tried to isolate herself from outside impressions; this she did under the influence of her mystic delusional ideas. Secondly, there was a distinct hysterical phase of the disease. For a detailed consideration of pathological sleep, particularly of hysterical nature, the author refers to Gilles de la Tourette's works.—*Journal of Medical Pathology.*

Kleptomania and Collectivism.—James G. Kiernan says that, in the vast majority of cases, kleptomania is a morbid manifestation of neuroses and psychoses, rather than a psychosis by itself. In many cases of so-called kleptomania, stealing is a manifestation of viciousness or feeble morality. The majority of cases of both these forms occur in the department stores. "Bargain sales" are determining factors of theft. Pregnant women are more apt to be predisposed to kleptomania than others, as are those who are menstruating, who are neurasthenic, alcoholic, opium eaters, hysterical, climacteric, and senile, from so great a weakening of the will that they fall ready victims to obsessions and morbid impulses. The "Collector" type of kleptomaniac, is, as a rule, perfectly responsible. "Book snatching" is a besetting vice of bibliomaniacs, just as coin and stamp purloining attacks numismatics and philatelists. Parisians think it "smart" to steal sugar and matches from restaurants. Not a few sane Americans think it is equally smart to steal rides on railroads.—*The Alienist and Neurologist.*

MARRIAGE AND MORTALITY.

AFTER citing the claim of Farr, based upon the statistics of France for 1853, that marriage is a "healthy estate," and that of Starr, Registrar-General of Scotland, that bachelor life is much more destructive to males than the most unwholesome trade or residence where not the most distant attempt at sanitation exists, Mr. Frederick L. Hoffman analyzes, in the *Spectator* for November 6 and 13, 1902, the statistics of the census of 1900 for the "registration area" (States and cities registering accurate vital statistics; population, 20,312,000) bearing upon this point. From his tables the following ones are made by combination, and by calculation upon a mortality of 1,000 married males as a basis; and, in the incompleted lines, a comparison of females, *inter se*, is given, calculated upon a mortality of 1,000 married females as a basis:

RELATIVE MORTALITY FROM ALL CAUSES.

	SINGLE		MARRIED		WIDOWED	
Ages.	Males.	Females.	Males.	Females.	Males.	Females.
15–44 ...	1,160	765	1,000	1,123	2,418	1,506
15–44		681	.....	1,000	.....	1,341
45–64 ...	1,632	1,069	1,000	853	1,843	1,216
45–64		1,253	... ..	1,000	.....	1,425
65.	1,437	1,183	1,000	873	1,552	1,183
65		1,354	.....	1,000	.....	1,354

From a study of the component tables Mr. Hoffman concludes: "These tables, though limited to essential facts and to periods rather too long for life insurance purposes, conclusively show that (1) the mortality of the single of both sexes is higher than the mortality of the married, and at all periods of life, except ages 15 to 44 for women; (2) the mortality of the single of both sexes is less at all periods of life than the mortality of those who are widows at ages under sixty-five, while at ages sixty-five and over the differences are too slight to indicate a definite law one way or the other; (3) the mortality of the married of both sexes is more favorable at all periods of life than the mortality of the widowed; (4) the mortality of single males is higher at all ages than the mortality of single females; the mortality of married males is higher than the mortality of married females, except in the age period 15 to 44, . . . ; (6) the mortality of widowers is higher than the mortality of widows at all periods of life." For the ages fifteen to forty-four years, the death rate for the married of both sexes is higher than that for the single, from all causes except consumption, but this lower rate for consumption more than balances the higher rates from other causes. Tumors are quite excessive in the married, especially women. The rate from nervous, circulatory, digestive, and urinary diseases is considerably higher in married than in single women, and a very important difference exists in the rate from diseases of the generative organs (2,555 married for every 1,000 single). The rate for the widowed of both sexes is higher than that for the married, from all causes. Among the widowed the rate from consumption is excessive (for men more than three times, for women more than one and one-half times, that for the married); other important differences are: for widowers a higher rate from circulatory diseases, and a much higher one from suicide, and for widows an excessive rate from nervous, circulatory, and urinary diseases. For the ages forty-five to sixty-four years the rate for the married is less than that for the single from all causes, except for married women a slight excess from digestive diseases. The most important variations are, for the married of both sexes a much lower rate from consumption, less liability of married men to suicide, and a lower rate for married than for single women from diseases of the generative organs. The rate for the widowed of both sexes is higher than that for the married from all causes except (for widows) that from diseases of the generative organs. Widowers show a much higher rate from consumption, and very pronouncedly higher rates from other causes; in widows the differences from the married standard are less marked, and are most pronounced for nervous, circulatory, and urinary diseases. From sixty-five years upward the rate for the married is less than that for the single, from all causes, except a slight increase for married women from diseases of the digestive and generative organs. The rate for the widowed of both sexes is higher than that for the married from all causes except consumption and tumors (in widows). Widowers show a higher rate from nervous, circulatory, and urinary diseases, and from suicide; widows show a higher rate from nervous and circulatory diseases.

So much for the figures. The moment, however, that we ask: What do these figures *mean*? we appreciate the wisdom of Mr. Hoffman's statement that "the general problem of marriage and longevity as distinct from the mortality rate could not be considered for want of space;" and, also, his limitation of his conclusions to the single one that "the present practice of companies of accepting risks on women, especially while in the pregnant state, may require to be materially modified." Such statistics are, thus, safe in Mr. Hoffman's hands. But, for ourselves, we gaze at such a tempting array much as in our childhood we were wont to gaze, wistfully, yet timorously, at a certain peanut stand over which hung the motto: "They say the Lord helps those that help themselves, but the Lord help any man caught helping himself here." On the whole, we incline to the belief that any one who wishes from these figures to extract a demonstration of the healthiness of marriage may find himself in a quandary. For obviously, what passes for the "mortality of the married" is in no sense its *true* mortality. The latter is clearly the "mortality of the married," as now reckoned, plus a certain, entirely indeterminate, fraction of what is here classed as the "mortality of the widowed;" that fraction, in short, which represents the mortality

due to causes which originated during the married state, and not during widowhood. Our Pension Office certainly would smile at a demonstration of the healthiness of military life, deduced by ignoring the future mortality of those discharged for disability. Here the case is peculiar in that the recruits of the matrimonial army are discharged therefrom, not by reason of any demonstrated unsoundness in themselves, but on account of that of the other partner; and the question is, therefore, utterly problematical as to what their physical status is at time of discharge into the ranks of the widowed. The extreme mortality of the latter class from consumption, however, looks suspicious. May it not be due to a more frequent transmission from husband to wife, and *vice versa*, than has hitherto been supposed. This suspicion receives a certain amount of support from the consideration that though the average age of the widowed must exceed that of the married the general prevalence of consumption does not increase with increasing age. These statistics are, at any rate, certainly a composite of several factors. To show the urgent need of analysis before any conclusions are drawn, we may assume that the majority of the single fall, at a guess, between fifteen and perhaps twenty-five or thirty; and that the majority of the married fall over twenty-three to twenty-five. Now if, as is probable, most marriages last at least as long as six years, then the minimum age for the widowed would be not far from thirty. But if this comes anywhere near the truth, then we are, in the tables, lumping together mortalities not only for single, married, and widowed, but also for ages fifteen twenty-five, twenty-five and upward, and thirty and upward. The greater mortality of the single from consumption may mean many things. Only for males at ages sixty-five years and upward does it exceed the sum of the mortalities of the married and widowed. Very possibly at different age periods it may have different causes. But after considerable thought there seem to be too many possibilities present to render further guessing profitable. We are content to have indicated a few of the fallacies which might be involved in hasty generalizations upon these data. Interesting and suggestive as they are, in their present form they prove little, and they need to be supplemented by detailed data for at least every decade (and a five-year period would be better) of life before any certain conclusions can be drawn. It was doubtless statistics which the poet had in mind when he recommended drinking deep or tasting not.

POLLUTION OF THE SOIL.

Dr. George Vivian Poore, Professor of the Principles and Practice of Medicine, University College, London, is one of the most widely known English authorities on matters relating to sanitation and hygiene. He is, moreover, endowed with the gift of expressing his ideas in well-chosen and apt language. Recently there has been published the Milroy Lectures, which were delivered by Dr. Poore in 1899, together with other papers on sanitation, by the same author.

Dr. Poore is a great believer in the efficacy of the soil as a germicide, and gives it as his opinion that enteric stools may, with reasonable safety, be applied to the surface of well-tilled soil. They must not, however, be mixed with antiseptics, and they must on no account be buried deeply. They should be placed only a few inches below the surface, and be lightly covered. "There is no evidence, so far as I am aware," remarks the writer, "that fæces—enteric or otherwise—treated in this way, have ever been productive of harm. The sooner the ground is planted with cabbage plants the better, and it must be borne in mind that, if the soil is to remain sweet, tillage and cropping are a *sine quâ non*, and it is probable that pathogenic microbes succumb in the process."

The arguments adduced, in support of these views, are somewhat as follows. Tillage admits air, and in turning over the ground the beneficent effect of sunlight has the opportunity to exert its influence. The rapidity with which fecal matter disappears in the earth depends upon circumstances, viz., the state of the soil as to tillage, the mass of fæces to be dealt with, and the weather. If the weather be warm, with occasional showers, it will be discovered, at the end of about three weeks, that the whole of the fæces and paper has become humified, and no longer offends the sense of sight or smell; the smell, indeed, seems to disappear in a few hours. Drought or frost delays humification, but continued wet weather delays this process the longest.

Dr. Poore asks what harm are fæces capable of doing when thus applied to the soil? They are not likely to be eaten or inhaled; they cannot be drunk, and nothing short of absolute proof, says the writer, would make him believe that the bacilli can pass downward to the subsoil water, because, in well-tilled soil, the harder it rains the tighter are the fæces locked up, and with them one must suppose the bacilli, so long as they continue to exist.

The result is that when humification is complete there is produced what the gardener calls "good, rich, black mould," the fertility of which is unequalled.

Dr. Poore believes that there is abundant evidence for advancing the statement that a well-tilled and well-nourished humus is an absolute protection to our subterranean water-supplies, and from the experience resulting from an experiment now in its eighteenth year, declares that the best return, agriculturally, is got by the immediate and daily application of fæces to the land, and that while the fecal matter is, in agricultural phrase, "ripening," one may get a crop of cabbages, and after the cabbages, anything and everything. Much has been said and written lately concerning polluted soil, and if all were to be believed, such a condition must be a serious menace to the health of the inhabitants of the modern manufacturing town. Dr. Poore, nevertheless, does not believe that, because the enteric microbe may under certain conditions exist in the soil, therefore this should be regarded as the natural lurking place of typhoid bacillus. Furthermore, he is convinced that the balance of effects resulting from the manuring of land must be in favor of health, and that there is no evidence of evil resulting from farming or gardening operations.

The New York Polyclinic Medical School and Hospital has established a night clinic for genitourinary diseases on Monday and Thursday evenings at 8 o'clock.

ACUTE PANCREATITIS.

Only during the past few years has it been recognized that pancreatitis gave to the observer a real though not well-defined clinical picture, and it is to Fitz of Boston that our thanks are due for first having reduced the subject to a more satisfactory basis. Previous to 1889, the occurrence of several varieties of pancreatitis had been noted by different observers, and the results of a number of autopsies had been given, but the subject remained in rather a chaotic condition until very recently, and there are still many doubtful points to be cleared up.

Clinically and pathologically the condition is extremely interesting, and worthy of careful analysis. In the past two or three years the number of cases reported in the journals has increased considerably and many painstaking autopsies have been described, so that we are familiar with pathological conditions, though our knowledge of the clinical signs of the disease is neither so complete, nor so accurate, as we could wish. However, enough cases have been seen to enable us to say that acute pancreatitis is a disease characterized by rapid or sudden onset of severe abdominal pain, usually epigastric, and by more or less severe collapse, with vomiting and constipation. The physical signs may be negative, or there may be epigastric resistance, tumefaction, and tenderness. Signs of peritonitis do not, as a rule, occur early. It is obvious that such symptoms might easily, and frequently do suggest, acute intestinal obstruction or perforation of a gastric or a duodenal ulcer, and, acting upon such an assumption, some surgeons have operated, with the result that they have found a swollen pancreas and a quantity of bile or blood-stained fluid in the peritoneal cavities, and no other signs of disease. Results in such cases, and also in cases in which an operation has been done for a presupposed pancreatitis, have been exceedingly bad, patients, as a rule, soon dying from collapse, peritonitis, or exhaustion. It is evident, therefore, since medicinal treatment can only combat symptoms, that our means for coping with this formidable condition are very ineffectual, though, in the histories of some of the cases treated surgically, a ray of hope for future improvement in results sometimes appears. For example, some patients appear to have died from acute peritonitis, after apparently doing well for a time. Better technique, or, perhaps, better fortune, might avoid this danger in future cases, and give us an opportunity of judging of the possible efficacy of laparotomy and drainage. Whatever efficacy surgical treatment may have must evidently depend upon the removal of inflammatory products by drainage, with the consequent opportunity for *vis medicatrix* to exert itself and permit the diseased organ to recover.

As to the causation of this disease, we are rather in the dark. Infection undoubtedly plays an important part in this particular, and previous inflammatory disease in the bile-ducts seems to have been noted in some cases, but we are not now able to say positively that any particular thing is the cause, and even if we were, the fact would be of more practical importance in assisting diagnosis than in assuring prophylaxis. Hepatic disease seems unquestionably to be a predisposing factor in the occurrence of acute pancreatitis, and in a number of autopsies gallstones have been found in the various situations in which such concretions occur. The varying degrees of acuteness of the inflammatory process is responsible for the differences in the gross and microscopic appearances of the pancreatic tissue, and to some extent, in the intensity of the symptoms. In some cases the inflammation is so violent that greater or lesser areas of the organ become gangrenous, while in others in which the inflammation is less severe the process assumes a hemorrhagic character, with minute hemorrhages through the pancreatic tissue, and a greater or less effusion of blood into the peritoneal cavity. In still other cases, the inflammation presents types of severity varying from what we have just outlined to cases in which the pathological process partakes more of the qualities of a severe congestion than an inflammation, and which may be often considered more properly as subacute instances of the disease. In the gangrenous and hemorrhagic forms of the disease our plans of treatment have proved of no avail, and there seems very little prospect that anything can be done for the unfortunate victims of the condition under consideration, but we may hope that in coping with the less severe varieties we may sometimes be successful in saving patients.

An interesting accompaniment of this and other serious changes in the pancreatic tissue is the occurrence of fat necrosis which occurs within a short time of any serious interference with the function of the gland. It has been observed many times in the course of acute pancreatitis, and seemingly would be seen always, except that some cases prove fatal before there is time for its development. We are apparently in a fair way to understand and therefore often to eliminate and observe abdominal disease when we are attempting to diagnosticate various conditions, and although we are not thereby necessarily enabled to do much with acute pancreatitis, our knowledge will, without doubt, be of service in combating other conditions. More study and experience will make our position stronger, but the pancreas is so deeply situated and its pathological processes are so obscure that we must confess that the outlook, from the therapeutic point of view, is not encouraging. There is, however, plenty of room for investigation of the pathological side of the question.

THE JUBILEE OF LISTER.

The *British Medical Journal* devotes its issue of December 13 almost wholly to a review of Lister's life, and to an appreciation of his labors in the interests of mankind and science. Distinguished surgeons from most of the European countries join with their British brethren in contributing their meed of praise and respect to the great discoverer whose jubilee has just gone by.

Among these articles, perhaps the one which deserves the closest attention, is that of Mr. W. Watson Cheyne, for the reason not only that he was a pupil of Lister, and therefore especially qualified to discuss his achievements, but also because he gives a most intelligent criticism of the principles which he propounded. Mr. Cheyne writes as follows: "In 1877, when Lister first came to London, he was still using carbolized gauze, oil-silk protective, carbolic spray, etc., but he was as before ever o

the search for improvements, and was continually advancing with the advance of scientific knowledge. The aim which he had constantly before him was the simplification of his methods and the avoidance of irritation of the wounds by the substances employed. Hence, at a later period, when corrosive sublimate was demonstrated to be a good antiseptic, he experimented very largely on its uses in surgery, and introduced a variety of gauzes, wools, etc., impregnated with various preparations of mercury, such as corrosive sublimate, mercury biniodide, etc., till he ultimately produced the dressing which is still largely used by many—namely, gauze impregnated with the double cyanide of mercury and zinc. He also steadily diminished the introduction of antiseptics into the wounds themselves, and from the time that weak solutions of corrosive sublimate were introduced he ceased to bring carbolic acid into the wounds, reserving it for the disinfection of the instruments and skin. Ultimately, when it was shown that the dust in the atmosphere contained essentially non-pathogenic organisms, and might therefore be disregarded in its effects on wounds, and also that the carbolic spray was ineffectual as a means of destroying the organisms in dust, he readily abandoned the spray. Indeed, for years he had been hoping to be able to do so, but had hesitated till the demonstration of the above facts was complete. These are the keynotes to all his later work on wound treatment—namely, attempts to get rid of all irritating antiseptics, to avoid the contact of antiseptics with the wounds as far as possible, and to find antiseptics which, if they do happen to come into contact with the wound, shall not irritate it. Indeed, the methods of treatment which are so much the fashion at the present time, the so-called aseptic methods, are simply continuations of Lister's work, and are the completion of the aim which he held before him. How far they are the most practical methods for general employment, or as useful as some admixture with the Listerian methods—that is, the limited use of antiseptics—is a question which is open to debate; but they are in no way a departure from, or improvement on, the principle which Lister was always striving to carry out."

Mr. Cheyne has expressed in words the feelings of the medical profession everywhere, that aseptic surgery of the present time is simply the natural development of the principles set forth by Lister, and that he, and he alone, is the father of the method.

In another part of the Lister Jubilee Number of the *British Medical Journal* is this paragraph: "A distinguished American surgeon said recently, that outside the surgical clinic the physiology laboratory forms the best training-ground for the modern surgeon. A physiological institute at the present day has to have not only chemical, physical, and microscopic, but also surgical rooms." "The success of many physiological researches," Pavlow writes, "is only attainable by application of Listerism as strict as the best and newest surgical clinic can employ. I am convinced," he says, "that it is only by the development of surgical operations on the alimentary canal that we can hope to understand the exquisite chemical work effected by it." But it would be redundant to continue to quote from the many tributes of veneration which have been offered to Lister from all parts of the world on the occasion of his completion of fifty years service in the medical profession. He is, undoubtedly, the most conspicuous and most widely-known figure in the scientific world to-day. His monument stands wherever there is a hospital or wherever an operation is performed. As to his personal qualities, he is like all really great men, modest and unassuming; not seeking gain, but content to have won enduring fame for his profession and himself as one of the greatest benefactors to the human race of all time.

Typhoid Fever and Other Illnesses Due to Oysters.

There have been, of course, numerous cases of typhoid fever which have been directly traced to the consumption of infected oysters. The fatalities at Winchester, England, a short time ago, following the eating of contaminated oysters, was a notable case in question, and has drawn the attention of medical men everywhere, and especially of bacteriologists, to the matter.

In the *Lancet* of December 6 is a report by Drs. John C. Thresh and F. L. Wood on an outbreak in Essex, England, of typhoid fever and other illnesses due to oysters. This report presents several features of interest, but, as space is limited, reference will be made but to one or two points therein. The authors, writing of a bacteriological examination of the supposedly infected shell-fish, say, "We obtained a number of oysters from the implicated beds, and from the liquid inside the shell of these oysters we isolated in one case a motile bacillus capable of growing in phenolated broth, of curdling milk, and producing indol, but which did not give gas bubbles in glucose gelatin, and from another oyster the typical bacillus coli communis. The spores of the bacillus enteritidis sporogenes could not be found in the shell liquid in either oyster. In the juice from the gastric gland the bacillus coli communis could not be demonstrated in either case, but in both the spores of the bacillus enteritidis, sporogenes, or of an organism which we could not differentiate therefrom, were easily discovered. The bacillus typhosus was not found. Whether the presence of either or both of these organisms in oysters indicates sewage pollution or not, it is at present impossible to say. The bacterial contents of the shells and organs of various shell-fish is a subject which requires investigation."

"For comparative purposes we obtained some native oysters from probably the most celebrated fattening grounds in England, and our examination yielded the following results: Oyster No. 1—(*a*) Liquid from the inside of the shell gave a negative result as regards the bacillus coli communis and the bacillus enteritidis sporogenes. (*b*) Juice from the gastric gland gave all the indications of bacillus enteritidis sporogenes. A motile bacillus grew in phenolated broth which curdled milk and produced indol in abundance, yet did not give gas bubbles in glucose gelatin. Oyster No. 2—(*a*) From the juice inside the shell the same motile bacillus which was found in No. 1 (*b*) was obtained, but no bacillus enteritidis sporogenes. (*b*) In juice from the gastric gland the same motile bacillus was present which was found in the liquid inside the shell. The culture gave every indication of the presence of bacillus enteritidis sporogenes. A few of these oysters were placed in sea water, to which a bouillon growth of the bacillus typhosus had been added. On the second day the oysters were taken out and placed in fresh pure sea water. An oyster was removed on the first, third, fifth, and seventh days, and the juice taken from the gastric fluid examined.

Up to the seventh day the specific bacillus could be recovered and identified, but not afterward. Our investigations on these lines are being carried further, but the results point to the necessity of being careful about drawing conclusions as to sewage pollution of shell-fish from the presence of organisms belonging to the coli group of the bacillus enteritidis sporogenes."

Drs. Thresh and Wood do not absolutely say—because their investigations do not permit them to draw definite conclusions—that the presence of the bacillus enteritidis sporogenes is not sufficient to infect shell-fish so as to render their consumption dangerous to human life, but they seem to infer that such is the case. At any rate, however, all are agreed that oyster beds should be so situated that no sewage pollution can infect them. They certainly should not be placed at the mouths of rivers which are liable to contamination in their course. It would appear that the proper place in which to grow and fatten oysters is in the sea, where sewage pollution cannot reach them.

The Early Diagnosis of Typhoid Fever by Culture on Gelose of Diluted Fecal Matter.

It is a trite saying that the early diagnosis of a disease is of the utmost importance, but it is so true that it will bear repetition. Many valuable lives have been lost through the inability of a physician to diagnose a malady correctly and quickly. Therefore any method which will aid in this result is worthy of notice.

The Paris correspondent of the *British Medical Journal* of December 20 writes as follows: "M. Chantemesse described in May last a method of gelo-diagnosis of typhoid fever. He has now communicated to the Académie de Médecine the results of research made in his wards on the bacteriological examination of the stools in typhoid fever.

"The method is as follows: 10 c. cm. of ordinary peptone-agar-agar—peptone 3, agar 2, water 100—is taken, and to this four drops of a 5-per-cent. carbolic-acid solution, lactose 20 centigrams, and 1 c. cm. of tincture of litmus are added. This mixture is melted in a water bath, and then run into a Petri dish, so as to form a layer 1 or 2 mm. in thickness. A camel's hair brush dipped in a dilute solution of suspected fecal matter is drawn successively over the surface of five or six dishes so prepared, without being redipped in the fecal solution. After twelve hours incubation the light violet tint of the peptone agar is sown with colonies, some rose—B. coli communis, and others blue—typhoid bacilli. These latter are immediately tested by the agglutination test. Since October 1, last, twenty-three patients entered the ward of Professor Chantemesse with the clinical diagnosis of typhoid fever. Of these five were kept for some days under observation as doubtful cases. In these the agglutination test had been negative, and the agar never once revealed the presence of typhoid bacilli in the stools. Of the remaining eighteen cases sixteen had already passed the stage of rising temperature, and showed nearly all the clinical symptoms of typhoid fever; two, however, were at the sixth and seventh day of infection respectively. As to the first sixteen cases, the serum diagnosis had been positive from the time of admission, and the agar diagnosis showed the presence of typhoid germs in quite large numbers of the stools. In the two remaining cases Widal's test was negative on admission, but became positive in one case after three days, and in the second cases after four days; in both these cases at the time of admission the presence of typhoid bacilli in the stools was clearly demonstrated by agar diagnosis." The method is also shown to be extremely valuable, as a means of ascertaining the length of time the typhoid bacilli live in the intestines, during the stages of and after recovery from the disease. From his experience of patients in his wards, and whose progress was followed after leaving the hospital, Professor Chantemesse proved by the agar test that in some cases cured for over a month the typhoid bacilli was still present in the stools. In this way, he thinks, may be explained the diffusion of infection and the apparently spontaneous occurrence of typhoid fever.

The gelo-diagnosis of typhoid fever, although not available to every physician, has, it would seem, its obvious uses. At least, a trial of the method would not be out of place in hospitals, or by any physician who has the necessary appliances to carry out the method.

Pathological Sleep.

Many instances have occurred in which persons have fallen into a sleep lasting for days, and cases have been reported in which sleep has continued for weeks. This excessive sleepiness has generally manifested itself in women, and has usually been regarded as a symptom of hysteria. The condition is, however, an accompaniment of various nervous and psychic diseases, as well as of disturbed metabolism.

Dr. Serge Soukhanoff, Privat-Docent at the University of Moscow, contributes an article on pathological sleep to the *Journal of Mental Pathology*, Vol. III. He says, in part, "In most instances pathological sleep is only part of a complexus of disturbances, of which epilepsy, hysteria, and other diseases are the representative pathological forms. Narcolepsy, which was considered in the past by some authors as an individual disease, is now looked upon as the symptom of some disease." The writer then describes a case of pathological sleepiness during the course of a psychosis.

The patient was an unmarried woman, twenty-three years of age, of inherited nervous and neurotic disposition, who, after exhibiting for some time symptoms of mental instability, became prone to sleeping spells. Between November, 1901, and December of the same year she had several well-defined pathological sleeps, lasting from thirty-eight hours to longer periods.

The point which Dr. Soukhanoff wishes to impress upon his readers, judging from the case he describes, is that, as pathological sleep is met with in hysterical subjects who are also afflicted with a mental disease, we should not consider pathological sleep as being of hysterical nature only. He would define pathological sleep as follows: "Pathological sleep may be divided into two principal groups: (1) Pathological sleep, due to an organic cerebral lesion—cerebral swelling, arteriosclerosis, senile involution, general paralysis, inflamed meninges, etc., and (2) pathological sleep without any anatomical basis. Into this class may be entered the following varieties of sleep: hysterical, epileptic, that due to intoxication, to imperfect metabolism, etc. To this group also belong the varieties of pathological sleep often met with in functional psychic disturbances. There is a form of this variety of pathological sleep which might be called pseudo—or apparent sleep. During such sleep, the patient keeps his eyes closed, remains immovable, does not answer questions addressed to him, takes no interest in his surroundings, does not take any food, except what is artificially introduced into his stomach, does not micturate voluntarily, remaining like an inert mass irresponsive, even

when carried from one place to another. It is possible, however, to differentiate this condition from that of real pathological sleep by the mode of breathing, and the reflex movements of the eyelids."

Dr. Soukhanoff finally concludes that the case of pathological sleep with which he had to deal was more due to psychic disturbance than to hysteria, as the sleep was more pronounced when the former affliction was present.

Military Hospitals and Female Nurses.

In the *Journal of the Association of Military Surgeons*, Capt. J. S. Kulp gives tables showing the personnel and bed capacity of some twenty-five civil hospitals of the world, the percentage of the personnel for every department of the hospital, and several tables showing similar data for the military hospitals of the various armies, and he embodies the results of his comparison in tables, which show the proper allowance of personnel, according to departments, the allowance, according to patients of each rank, and the relation of personnel to bed capacity. Incidentally, the returns from the various hospital superintendents involved some interesting opinions relative to the strong points, and the limitations of nurses, male and female. The good qualities of the latter are superior education, cheapness, considering the high standard of work, social adaptability, refinement, temperance, morality, cleanliness of self and surroundings, and excellent habits. The disadvantages are those dependent upon her sex, greater expense in military hospitals, separate apartments and better food, and especially the difficulty of properly training hospital corps men serving along with women. Moreover, in military hospitals women cannot be utilized without the coöperation of the sanitary soldier, and not at all in battle, on the march, or even on the tented field; but in large base hospitals they will always be an important factor, and in emergencies can be obtained in adequate number.

Opinions are cited to the effect that on the *Maine* female nurses were found entirely out of place; the sick in South Africa endured two plagues—flies and women; and at posts, despite the wisest regulations and perhaps without fault of theirs, female nurses will now and then be a demoralizing factor, and should be employed only at large hospitals, and never fewer than two or three together. The hospital corps private drinks, his amusements are not refined, his home influences have not been of the best, his language is sometimes ungrammatical and frequently profane, his loves are—but, as Captain Kulp says, they are of his life a thing apart, and he is seldom on the sick list, except for cause, and can be counted upon in the time of need; in short, the intelligent, upright sanitary soldier is more and more in evidence, and upon him the service must, in the last analysis, depend.

The Use of Benzoyl-Acetyl Peroxide as an Intestinal Antiseptic in Cholera and Dysentery.

Dr. Paul C. Freer, Superintendent of United States Government Laboratories, writes from Manila concerning the preparation of benzoyl-acetyl peroxide, and its use as an intestinal antiseptic in cholera and dysentery.

After preliminary experiments, conducted in a small emergency hospital, the treatment of cholera at the tent hospital at San Lazaro divided itself into two methods: (1) The administration of benzoyl-acetyl peroxide in solution and in capsules, as an intestinal antiseptic for the destruction of the bacilli; and (2) the administration of stimulants, to enable the patient to survive, if possible, the effect of the toxin already present.

The solution given by the mouth, having been found, if persisted in, to produce protracted vomiting, was discontinued, and high rectal injections of 1 to 1,000 solution were given every four hours during the acute stage of the disease. This treatment seemed to give relief, and was largely due to mechanical action, from the sudden dilation of the large intestine, but, as shown in subsequent hospital experience, benzoyl-acetyl peroxide has also a stimulating effect.

Dr. Thos. R. Marshall, who had charge of another tent hospital, adopted three methods of treatment for cholera: (1) Benzoyl-acetyl peroxide; (2) the solution mixed with other remedies, and (3) remedies other than benzoyl-acetyl peroxide. The most efficacious mode of administration was found to be by rectal injections of 1 to 1,000 solution, mixed with a normal salt solution of equal quantity. At the Santiago Hospital, under the charge of Drs. Southall and Lindley, where benzoyl-acetyl peroxide was given the most exhaustive and extended trial, the results worked out as follows: The guaiacol carbonate and calomel treatment was used in fifty-four cases, and showed a percentage of recoveries of 14.18; against this, benzoyl-acetyl peroxide, mixed with guaiacol carbonate and calomel, had a total recovery of 41.94 per cent., and benzoyl-acetyl peroxide alone of 40.42 per cent. Four hundred and eight cases were treated with either benzoyl-acetyl peroxide or the same mixed with guaiacol carbonate and calomel, and of these 169 recovered; 593 received other treatment, and of these only 106 recovered.

With regard to benzoyl-acetyl peroxide in amœbic dysentery, Dr. Freer reports that its use has been attended with very beneficial effects.

Dr. R. P. Strong of the Biological Laboratory, Manila, thus writes with respect to the properties of the preparation: "Quinine used in enemata has hitherto usually given the best results in the treatment of amœbic dysentery. The advantages of benzoyl-acetyl peroxide over quinine, however, are apparent, for the latter, while quite capable of killing amœbæ, even in dilute solutions, also attacks the bacteria which are present in the intestines, and it has been found possible, by its use, to reduce greatly the number of microorganisms in the stools."

It may then be said that, upon the whole, the experiments undertaken in Manila with the view of testing the efficacy of benzoyl-acetyl peroxide in the treatment of cholera and dysentery have been attended with a considerable amount of success. The preparation has, probably, proved its value as an intestinal antiseptic in these diseases.

Preservatives in Food.—Dr. Pavy, replying to an inquiry of the *Lancet*, said that, because there was no tangible evidence of injury to health from the use of preservatives he did not consider that our knowledge is sufficient to say that the indiscriminate use of antiseptics will not produce injury. By the use of antiseptics it is the vendor and not the consumer who is benefited, as articles which are not fresh are made to appear so, and to continue this was an injustice to the consumer and the seller of the fresh article. He said that most articles, when properly made and handled, did not require the addition of an antiseptic; and when the antiseptic was added the article was not sold on its merits. He said that justice to all concerned required that the presence of antiseptics be plainly stamped on the article sold, so the buyer and consumer would not be deceived.

News of the Week

American Association for the Advancement of Science.—The fifty-second annual meeting of this association was held in Washington during the present week under the presidency of Dr. Ira Remsen. The opening session on Monday was held in the auditorium of Old St. Matthews Church, with the largest attendance of any convention since the formation of the society. The meeting was called to order by the retiring president, Prof. Asaph Hall, U. S. N., who introduced the president-elect, Dr. Ira Remsen. There were addresses of welcome by Dr. Charles D. Walcott, director of the United States Geological Survey, on behalf of the Washington Academy of Sciences and other scientific societies; Henry B. F. MacFarland, president of the Board of District Commissioners, on behalf of the city of Washington; the Hon. David J. Hill, Assistant Secretary of State, on behalf of the National Government, and Dr. Charles W. Needham, president of Columbian University, on behalf of the educationl institutions of Washington.

Plague in Mexico.—A disease of peculiar character appeared recently at Mazatlan, on the Pacific coast of Mexico, which was suspected to be bubonic plague. This suspicion has now been confirmed by the results of bacteriological investigation, and the presence of the plague in the city is officially admitted. The disease at first appeared to be of a mild type, but it has since assumed a more virulent form and almost a panic has arisen in the city. The towns in the interior of the country on the lines of travel from Mazatlan have declared a shotgun quarantine against the city, and the entrance of refugees has been forbidden. The majority of sufferers from the plague are women. Two cases have also been reported in the town of Ahome, in the State of Sinaloa, near the Sonora border.

Coroners and Coroners' Physicians.—Justice Leventritt recently vacated the writ of prohibition obtained by Coroners' Physician Albert T. Weston to restrain the Board of Coroners of this borough from removing him. Justice Leventritt holds that under the present charter the coroners of each borough can act independently. He also finds that the term of office of a coroners' physician is co-terminous with that of the coroner making the appointment, and that Dr. Weston's term evidently expired, as the coroners contend, on January 1, 1902, when the old board went out.

The Canton, Ohio, Medical Society held its third annual banquet at the new Hotel McKinley on Friday, January 9, covers being laid for a hundred guests. Dr. Daniel Milliken of Hamilton, ex-President of the Ohio State Society, made the chief address. Officers elected for the ensuing year are: *President*, A. V. Smith; *Vice-President*, F. E. Hart; *Recording Secretary*, Harry A. March; *Corresponding Secretary*, D. F. Banker; *Treasurer*, F. A. Dahinden; *Censors*, J. F. Fraunfelter, E. O. Portmann, and A. C. Brant. The Society is in an exceedingly prosperous condition, and has been granted an alcove room in the new Carnegie library building in process of construction.

The Lincoln Hospital.—With a new name and new buildings in a new location, the character of the institution founded in 1830, and familiarly known as the Colored Home and Hospital has undergone a noticeable change. The new hospital buildings are situated on One hundred and forty-first street, near the Southern Boulevard, and provide accommodations for over three hundred patients. The main building is in the shape of the letter H, and gives space for four wards on a floor, with light on three sides. Excellent provision is made for the care of consumptives in a two-story building detached from the main one. Another separate building contains a modern and well-appointed maternity service, while two other small ones house the isolating rooms and laboratories, the boiler rooms and the laundry. The change in the name of the hospital was forced upon the managers in a peculiar and unexpected way. When the hospital was opened in the borough of the Bronx the city desired it to establish an ambulance service in that district. This was done, and, as a result, it was not long before the proportion of colored people in the acute wards was no more than in other hospitals. A training school for colored nurses is a novel and successful feature of the hospital.

Society of College Gymnasium Directors.—The sixth annual meeting of this society was held last week in the New York Athletic Club building. The following officers were elected: *President*, Dr. Watson L. Savage, Columbia University; *Vice-Presidents*, Dr. Jay W. Seaver, Yale University, and Dr. W. A. Lambeth, University of Virginia; *Secretary* and *Treasurer*, Dr. James A. Babbitt, Haverford College; *Council*, the officers ex-officio, Dr. R. T. McKenzie, McGill University, and Dr. Paul C. Phillips, Amherst College; *Executive Committee*, Dr. J. E. Reycroft, University of Chicago; Dr. D. A. Sargent, Harvard University; and Dr. W. G. Anderson, Yale University. A special committee on the revision of all statistics and phases of physical examination was also appointed, consisting of Dr. Savage, Dr. Sargent, Mr. Marvel of Wesleyan University, Dr. Phillips, and Dr. Reycroft. The next meeting will be held at Princeton, N. J.

A Hospital for "Bloodless Surgery."—The "Lorenz Orthopedic Charity Hospital of New York City" has asked the State Board of Charities for approval of its certificate of incorporation. Its object is to establish a free hospital or dispensary for the treatment of persons afflicted with deformities, especially congenital dislocation of the hip, according to the Lorenz method. The incorporators are William S. Brewer, Charles F. Smith, Franklyn E. Sylvester, D. Baldwin Sanneman, and Benjamin F. Curtis of New York.

A Typhoid Epidemic from Infected Oysters.—An epidemic of typhoid fever appeared about the middle of December at Portsmouth, Southampton, and other towns on the southern coast of England. The disease was traced directly to oysters which had been fattened near the mouth of a sewer at Emsworth. The spread of the epidemic to many towns followed a mayoral banquet at Southampton, which was attended by many of the higher officials and clergy from neighboring towns, and at which the infected oysters were served.

Lemon-juice Inimical to the Typhoid Bacillus.—A cable despatch announced recently that Dr. Asa Ferguson of London had discovered that lemon-juice would destroy the typhoid bacillus. The Chicago Commissioner of Health at once began a series of experiments which showed that this claim was correct. The following experiment was made in the laboratory to test the value of lemon-juice in destroying the typhoid bacilli: One hundred and twenty c.c. of bouillon was inoculated with the bacillus typhosus. The flask was placed in the incubator at 90° for twelve hours. At the end of this period 4 c.c. of lemon-juice was added. At the end of four hours plates were inoculated from this flask. The plates at the end of twenty-four

hours showed no growth. Control plates showed abundant growth. The value of the discovery does not, however, appear to be very great, for if two teaspoonfuls of lemon-juice must be added to a glass of water four hours before the water can be drank with impunity, it will be simpler, and probably safer as well, to stick to the "tea-kettle" policy, or take only distilled water, as at present advised.

Philadelphia County Medical Society.—At a stated meeting, held December 23, Dr. Anna M. Reynolds read a paper entitled "Twin Pregnancy, Polyhydramnious and Eclampsia-Monstrosity." Drs. J. H. Lloyd and T. L. Coley read a paper entitled "Two Cases of Typhoid Fever with Inconclusive Symptoms; Perforation." Dr. A. P. Francine presented a communication on "Physical Signs and Symptoms of Gastroptosis."

Philadelphia Neurological Society.—At a stated meeting, held December 23, Dr. S. Weir Mitchell read a paper entitled "Notes on Obsessions and Reversals of Volitions." He referred to a number of cases in individuals, some of whom presented also symptoms of mental derangement, while others did not, and who were at times impelled to do the opposite or the reverse of the thing they intended to do, such as going down stairs instead of up, walking backward instead of forward, reversing the letters of spoken words, putting shoes on the hands and gloves on the feet, pulling the shirt on from below, and the drawers on from above, the utterance of expressions the opposite of what was thought or intended. He spoke also of what he designated despotic habits, representing figuratively a form of mantel tic, namely, acts of one sort or another, failure to do which gives rise to a sense of discomfort. Dr. Wm. Pickett exhibited two patients with paresis, one of circular type and the other with double personality. The first patient, who had a psychotic family history, after having passed the preliminary neurasthenoid stage and the following expansive stage, entered, after an interval of quiescence, upon a stage of profound melancholia, although inequality and immobility of pupils on exposure to light and absence of knee-jerks persisted. In the second case the patient was affected by the delusion that there was constantly upon his back a second person, who said and did a number of things attributed to the patient, and for whom the patient put aside regularly a certain portion of his own food. Dr. Pickett also reported a case of paresis with a remission that had lasted nearly four years. Dr. Alfred Gordon exhibited a case of amyotrophic lateral sclerosis in a boy of fifteen years who had had an attack of acute anterior poliomyelitis in infancy. The attack of infantile palsy had occurred when the child was one year old and had left weakness and wasting of both lower extremities, while the symptoms of amyotrophic sclerosis had begun to make their appearance at about the age of eight years in the sequence of some infectious disease. Seven years later weakness and wasting, with increase in reflex activity, appeared in the upper extremities and the shoulder girdle. The right humerus had been fractured twice from causes that ordinarily would be inadequate. Dr. Chas. W. Burr and Ralph S. Lavenson read a paper entitled "Report of a Case of Tumor of the Brain." The patient had been a woman with carcinoma of the breast, in whom spasm in the left upper extremity, persisting for long periods of time, recurred at varying intervals. On post-mortem examination, apparently a metastatic nodule was found in the ascending parietal frontal convolution of the right cerebral hemisphere. Dr. F. Savary Pearse presented a communication entitled "Double Consciousness or Amnesia; Etiological Factors, with Report of a Case." The patient was a young man who, following concussion in a trolley accident, wandered away from home a considerable distance, and for a period of three and one-fourth years was entirely unconscious of his previous existence, and subsequently entered upon a stage in which he lost all memory of that which had transpired during this period. There had been no convulsion and no other symptoms of epilepsy, and also no hysterical stigmata. Dr. T. H. Weisenburg reported a case of gumma of the brain with operation. The patient presented symptoms of hemiparesis with epileptiform convulsions. Temporary relief was afforded by the operation, but after a time symptoms of recurrence developed.

Spencer on Vegetarianism.—Herbert Spencer is poking fun at the vegetarians of England, and has taken them completely by surprise, inasmuch as they thought they could claim the philosopher as one of their own. Mr. Spencer does not apparently think highly of the mental state produced by a year of vegetable diet. He said recently: "I went over all I had written during the year I practised vegetarianism, and consigned it all to the fire." Since then he has been saying some facetious things about the "devotees of the truck garden," as he calls the vegetarians.

The Late Dr. Byrne.—The following resolution was passed at the meeting of the New York Obstetrical Society, held December 9, 1902:

Resolved, That by the death of Dr. John Byrne, our oldest Honorary Fellow, the members of this society have lost a beloved associate, whom we esteemed as an eminent surgeon, a wise counselor, and a faithful friend.

CHARLES JEWETT, M.D.
HENRY C. COE, M.D. } Committee.

Obituary Notes.—Dr. WILLIAM R. GROVE died at Columbia, Pa., on January 3, at the age of sixty-five years. He was a graduate of the University of Maryland School of Medicine in 1865.

Dr. JULIUS KOHL died at his home in Belleville, Ills., on January 2, of cancer of the stomach. He was a graduate of the St. Louis Medical College in 1859. He was an ex-member of the Illinois State Board of Health.

Dr. CARL SCHUMACHER, a homœopathic physician of Syracuse, died on January 2 from the results of a fall on the sidewalk about two weeks before. He was a graduate of a Cleveland college in 1883.

Dr. DAVID JACOBSON of Brooklyn died on December 31 in a hotel in this city. He was born October 4, 1864, and was graduated from the New York University Medical School in 1888.

Dr. DENNIS J. LOUGHLIN died at Philadelphia on December 27 at the age of fifty-five years. He was a graduate of Jefferson Medical College in 1881. During President Cleveland's first administration he served as appraiser of drugs, and during Cleveland's second term was appointed pension examiner, a position he held until his death.

An Ominous Combination of Names.—A few days ago a Miss Death was brought to the German Hospital to be operated upon for appendicitis. She was a daughter, she said, of an undertaker. The surgeon's name who was chosen to perform the operation was Dye. When the operation was over Miss Death was placed in charge of two nurses, Miss Payne is the day nurse; Miss Grone is the night nurse. The patient is recovering rapidly, and in a week or so Miss Death will bid good-by to Dr. Dye, Miss Payne, and Miss Grone.—*Philadelphia Public Ledger.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE LORD LIEUTENANT AND THE DOCTORS—ANOTHER OUTBREAK OF TYPHOID FEVER FROM CONTAMINATED OYSTERS—HÆMATEMESIS, MEDICAL DISCUSSION, SURGICAL—RECENT DEATHS.

London, December 19, 1902.

The Countess of Dudley made such steady progress, that on Monday the Earl fulfilled an engagement to open the new buildings of the Adelaide Hospital. His Excellency took the opportunity of expressing the deep debt of gratitude he felt to the medical profession, and declared that if, during his residence in Ireland, he was able to show that gratitude, in connection with hospitals or the profession, the appeal would not be made to him in vain.

The manner in which the Dublin leaders of the profession have maintained their dignity over this case, is an excellent example to some of the attendants on distinguished persons nearer home. There has been no fussiness, no interviewing, no communication of gossip to the press. The surgeons and physicians have quietly done their duty; issued only the necessary bulletins, and yesterday announced that one as the last, if the progress continues as heretofore.

Outbreaks of typhoid fever at Portsmouth and Southampton are reported to be due to sewage contamination of the oyster beds at Emsworth. Dr. England, formerly physician to the Royal Hampshire Hospital, has succumbed to the disease, and a number of distinguished persons, who attended a dinner at Winchester, when Emsworth oysters were served, are lying ill.

And yet the event could have been predicted. In 1895 Dr. Bulstrode, inspector to the Local Government Board, reported that the oyster bed in question could not escape pollution by sewage. It is said that some attempt to intercept the sewage was then made, but it seems to have been no one's duty to see that this was properly done, and it was not. So now another outbreak has occurred, and the Local Government Board has sent Dr. Bulstrode again to make another inspection and report.

Two evenings have been devoted, by the medical society, to the discussion of hæmatemesis—the first to the medical aspects of the disease, the second to the question of surgical treatment.

The first discussion was opened by Dr. Bertrand Dawson, in a paper on the pathology, prognosis, and medical treatment. He said it was not possible in any given case to determine the source of the bleeding, which might be focal, from one vessel, or diffused, from several. In portal obstruction the source was most commonly the œsophageal veins. In forty-two cases of cirrhosis of the liver, in which these veins were examined, they were dilated in thirty-five, and in sixteen of these the apertures were seen. In the case of young anæmic women fatal oozing might occur from superficial erosions, and these might precede ulceration. With regard to so-called vicarious menstruation, there was a wide-spread tendency to hemorrhages from mucous surfaces during the menstrual period. As to the medical treatment, it was only rarely necessary to feed per rectum. Morphine, ¼ gr., should be injected hypodermically. Chloride of calcium could be given per rectum. Ergot, hypodermically, was not recommended. Adrenalin was better. When a very great quantity of blood was lost, normal saline solution, injected under the skin, had been useful. These measures succeed in 90 per cent. of the cases of hæmatemesis, and should, therefore, always be tried before resort to surgery, but in very acute cases, almost certainly due to gastric ulcer, an operation might be undertaken.

In the course of the discussion, Professor Osler's "anæmia splenica" was referred to, and one case, in which excision of the spleen was followed by fatal hæmatemesis, perhaps produced by venous engorgement of the cardiac end of the stomach, through the ligation of the splenic vein.

Rest and opium were held to be the most important points. The late Sir Wm. Jenner had great faith in gallic acid. Ergotin was not considered of much use. Doctor Yeo found perchloride of iron and nitrate of silver beneficial—the latter especially when erosion was suspected. Adrenalin he thought too apt to raise general arterial tension. Gelatin, subcutaneously, had, in some cases, produced ill results. Food was often pressed too soon, patients could do without any for several days.

Dr. Hale White disputed the statement that the mortality of gastric ulcer was five times more frequent in women than in men, and believed it more common in men.

In women from twenty to thirty-five years of age, dyspepsia, anæmia, and hæmatemesis might be present without any ulceration. Perhaps such cases were a form of chlorosis. He advised ½-dr. doses of iron perchloride with as much glycerin.

Dr. Rolleston referred to the minute erosion described by Murchison, Dieulafoy, and Lindsay Stevens—the "pore-like erosion" of gastric arteries. This was, perhaps, the condition referred to by Doctor White. It differed clinically from gastric ulcer, by the absence of tenderness, but set up profuse and often fatal hemorrhages. In giving rest to the stomach by rectal feeding, water must not be permitted by the mouth; it might set up peristalsis.

The second discussion, that on surgical treatment, was opened by Mr. Mayo Robson, who entered rather fully on the different classes of cases met with, and related ten cases as illustrations. Recognizing the frequency with which medical treatment is successful, he thought that went to show how often capillary oozing accounts for the bleeding. At the same time he would not forget how rapidly fatal hemorrhage from large-sized arteries might be. He would always have medical treatment fully tried before surgery, but when it failed he would not stand by and watch a patient die who might be saved by operation. Of the various operations available, he preferred gastroenterostomy, which can be done expeditiously, without severe shock, and which drains the stomach into the jejunum, relieving hyperacidity of the stomach, and giving it physiological rest. As a rule this operation arrests the bleeding, and cures the disease, which gives rise to it. If there be no sign of ulceration found on the stomach wall, he is content with gastroenterostomy, but if there be any evidence of a chronic ulcer where it can be reached safely, excision of the ulcer should precede gastroenterostomy. If tumor of the pylorus appear, pylorectomy may be necessary. If the ulcer adhere to or erode the spleen, nothing but simple gastroenterostomy should be attempted.

Several surgeons contributed remarks on the paper, but none of them went to invalidate Mr. Robson's conclusions, which, in fact, were generally accepted.

Dr. Samuel Fenwick, consulting physician to the London Hospital, died on the 11th inst., aged eighty-one years. He was born in Northumberland, and for some years practised in that county. He received the M.D. degree of Durham in 1859, being lecturer on pathology at the medical school. He had previously graduated at St. Andrews. Some forty years ago he came to London and was elected on the staff of the London Hospital and the City Hospital for Chest Diseases. At the London Hospital he taught pathology and later medicine. He was elected F.R.C.P. in 1870. His little manual of diagnosis must be known to you; it had a very large circulation. But his *magnum opus* was that on diseases of the stomach.

The deaths are also announced of Dr. Thos. Shapter of Exeter, many years physician to the hospital and a leader in the west of England, in his ninety-fourth year. Dr. John Lowe, physician extraordinary to the King; he was called to attend the Prince of Wales in 1871 for what was thought a trifling indisposition, but suspected typhoid fever, and history tells he was right. Mr. E. D. Hacon, F.R.C.S., aged eighty-four years. Dr. John Lloyd, formerly professor at Queens College, Birmingham, aged seventy-six years. Dr. John Young, Professor of Natural History in Glasgow University, and curator of its Hunterian Museum.

PHOTOTHERAPHY AND PHOTOGRAPHING THROUGH THE BODY.

To the Editor of the Medical Record:

Sir: My attention has been called to a letter by Dr. Hopkins of Brooklyn concerning my article in your issue of November 1, in which the writer erroneously states that the reflector designed by me and made use of here condenses but little or no light.

The violet colored light condensed by it is as strong as can be borne by the patient on account of the accompanying heat. It is entirely impossible to separate all the heat from the light from any source. In constructing any device for the concentration of light upon the body this fact cannot be lost sight of. Otherwise we might turn almost any volume of light upon the patient. The writer is also confused in regard to the construction of the apparatus used by me and that by Dr. Finsen. The one is a reflector, the other a lens.

While writing, permit me to at least make the attempt to keep the Medical Record straight in regard to photographing through the human body. The first announcement of this procedure was published in the Medical Record on October 13, 1900, when I detailed the steps taken by myself and photographer, G. L. Hostetler of this city. In April, 1902, Gottheil and Franklin of New York published in the Medical Record a paper in which they traversed in every particular the steps taken by us two years before, and in

which they claim the work as original. During 1902 Mount Bleyer of New York published an article in the *Journal of Tuberculosis* detailing the same thing, in which he likewise claimed priority. Recently Kaiser of Vienna has done the same thing.

The arrangement of the picture on glass over the sensitized plate for the purpose of reproducing the picture by means of light which had first traversed the thickness of the body, was original with Mr. Hostetler, the writer having in mind only the blackening of a sensitized plate by means of such light. Mr. Hostetler then suggested this arrangement of the plates for the production of the picture, and it is at least a strange coincidence that four other writers thought of the same thing almost two years later.

J. W. KIME, M.D.

FORT DODGE, IA., December 27, 1902.

SYPHILIS IN THE BARBER SHOP.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Dr. A. Jacobi's letter (page 986 of your issue of December 20, 1902), concerning my article on "Syphilis in the Barber Shop" (MEDICAL RECORD, December 13, 1902), is certainly of qualified interest, it being simply a quotation from Proksch's recent book of the "Study of the History of Medicine." It is, however, a relic of medieval history, and is an illustration of the wonderful erudition of the indefatigable Proksch; but the quotation is utterly irrelevant to the facts and suggestions brought out by my little paper. In that I bring up a live and pertinent issue, and call attention to the need of more restrictions and prophylaxis among barbers in barber shops. On the other hand, Proksch's excerpt deals with the ignorance of medieval practitioners of minor surgery, variously styled "surgeons barbers," "barbers," "leechers," "cuppers," and "sangrados." There are no such practitioners to-day!

It may be interesting to the readers of the MEDICAL RECORD to know that there are many cases reported in medical literature within the past thirty or more years of syphilitic initial lesions on the chin, cheek, neck, lips, and angle of jaws, which originated in a razor cut, and that in many instances, on examination and study, the infection by the barber was rendered conclusive—while in many others it was very probable, and suspicions were warranted in others.

The following is a list of the writers of the chief papers on the subject of razor syphilis: Aubert, 1878; Broick, 1888; Carre, 1866; Cripps, 1892; Flibe, 1889; Fedchenko, 1889; Fluscher, 1886; Fournier, 1885; Giovannini, 1889; Gluck, 1881; Goldenberg, 1890; Idelson, 1888; Koltchewski, 1881; Mauriac, 1880; Nekolsky, 1891; Tarnowsky, 1891; Taylor, 1893; Tchudnowsky, 1889, and Van Harlingen, 1885.

A. FANONI, M.D.

NEW YORK.

THE AMERICAN SCHOOL OF MEDICINE, BEYROUT, SYRIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In May of last year I visited Beyrout and saw a great deal of the medical department of the Syrian Protestant College. I can heartily endorse all that was said by Professor Schauffler in your issue of December 27. The Faculty of the school are men of eminence, and the whole spirit of the school is of the very best character. I can commend it in the highest terms. If the plans that are in contemplation for its enlargement are carried out, it will be but a short time before it will supply most of the countries of the East with thoroughly equipped medical men.

W. W. KEEN, M.D.

PHILADELPHIA, January 5, 1903.

Physiological Researches on the Effects of Section of the Cervical Sympathetic.—Moussu and Charrin draw the following conclusions from their experiments: (1) Section of the sympathetic produces in the patient an undeniable, but very slight, modification of the physiognomy. (2) This modification of the external appearance does not cause constant and important trophic troubles. Without wishing to make a close comparison between what has been noted in the animals experimented upon, and that which occurs in man, it stands to reason that the changes will be more marked in the human face, which is more complex. Nevertheless, as the disorders are of little consequence, the writer believes that if in certain pathological conditions, section of the sympathetic will lead to amelioration of the trouble, fear of trophic disorders should not constitute, perchance, a sufficient reason for abstaining from the operation.—*Le Bulletin Médical*, December 10, 1902.

An Antiserum for Morphine Poisoning.—Leo Hirschlaff has obtained an anti-morphine serum by treating rabbits with daily increasing doses of morphine until very large doses were borne with impunity. The serum obtained from animals thus treated was able to protect new animals completely from many times the fatal dose of morphine. Ample control experiments were also conducted, so that the results obtained can in no way be doubted. Only one case of acute morphine poisoning in the human being has been treated by this serum. The result obtained was excellent, although additional treatment, such as atropine and caffeine, was given, so that the actual efficiency of the serum was not thoroughly tested. The serum has been used in five cases of chronic morphine poisoning with very encouraging results. All of these cases were habitués, and in them, under the influence of the serum, the morphine could be withdrawn with great rapidity. The usual dose of the serum was 5 c.c., but it is probable that 10 c.c. in acute cases is a more suitable amount. Its real value can only be ascertained by a more extended use.—*Berliner klinische Wochenschrift, December 15, 1902.*

Urine of Cancer Patients.—J. Sabrazès states that one conceives *a priori* that the modifications of the humors of the organism in case of cancer ought to vary with the nature of the neoplasm, and with its location. The examination of the blood and urine, from this point of view, justifies this opinion. According to Blumenthal, indicanuria of a very high degree militates in favor of carcinoma of the stomach, and of ulcerated cancer, when there exists albuminuria and a positive diazo-reaction. The appearance of an intense glycosuria, during the evolution of a neoplasm, indicates a pancreatic localization, as the writer has recently noted in the course of a gastric neoplasm generalized in other abdominal viscera, or it may mark the development of a tumor in the region of the fourth ventricle. Lactic acid urinary secretion augurs in favor of cancer of the liver; increase of the amount of uric acid, in favor of a tumor of an organ rich in nuclein—liver, pancreas, thyroid body, ganglia—and in favor of one of the affections so closely related, in the opinion of the writer, to neoplasms, myeloleucocythemia, and lymphocythemia.—*Gazette Hebdomadaire des Sciences Médicales*, December 7, 1902.

Suppurative Meningitis from the Colibacillus.—Nobécourt and Du Pasquier report this case of a child of seven months, who was brought to the hospital for an acute gastrointestinal infection, with green diarrhœa and slight fever. Then appeared convulsions, contractions, disorders of respiration and circulation, which established the diagnosis of meningitis. Lumbar puncture revealed an increase of cerebrospinal liquid. Then the symptoms improved, and the fever had disappeared four days after the admission to the hospital. This was only temporary, for the temperature rose, and phenomena of intestinal infection showed themselves anew. On the fifth day of this recrudescence, meningitic symptoms reappeared, and this time lumbar puncture confirmed the diagnosis of suppurative meningitis, due to the colibacillus. The condition became very grave, but recovery terminated the illness, thirty days after admission to the hospital, and twenty days after the diagnosis had been clearly established. In regard to the symptoms, this meningitis presented nothing in particular. Its beginning was sudden. It was by lumbar puncture alone that diagnosis of the microbic nature of the meningitis was clearly established. Recovery from this form of meningitis is very exceptional. —*Gazette Hebdomadaire de Médecine et de Chirurgie*, December 7, 1902.

The Employment of Massage in Tabes.—M. G. Constensoux concludes: (1) The employment of massage in cases of tabes ought to be specialized and adapted to the indications of each particular case. (2) According to the movements employed, and the applications which are made, massage is useful in certain cases, but may also be harmful. (3) It ought, then, to be practised either by a physician who is an expert in the treatment of this disease, or by a masseur who is absolutely obedient to the instructions which he receives. (4) The indications for massage in tabes are as a general tonic; as a proper means of combating certain troubles of sensation; in case of certain complications. (5) Massage of the skin is useful in troubles of sensation, and as a general tonic for exciting nutritive changes. (6) Massage of the muscles is without effect on ataxia; it is fatiguing to patients when it is energetically performed; it should be used only in paralysis or true atrophy. (7) Passive motion is contraindicated in the case of articulations already too mobile, and of hypotonic muscles. (8) Whatever may be the conditions, the movements of massage ought always to be gentle, and the treatments short in cases of tabes. There are patients who should avoid fatigue, against which they are badly defended by their physical condition.—*La Presse Médicale*, December 6, 1902.

Book Reviews.

Recherches Cliniques et Thérapeutiques sur l'Epilepsie, l'Hystérie et l'Idiotie. Par Bourneville. Vol. XXI. Paris: Bureaux aux Progrès Médical, 1901.

The present volume is the twenty-first of a series of researches upon epilepsy, hysteria, and idiocy published under the direction of Bourneville. It contains in the first part a history of the work done in the year 1900, and in the second part some clinical and pathological studies. The first part is of special interest to administrators of such hospitals as that which Dr. Bourneville directs, but it contains also a great many interesting statistics regarding the pedagogical methods employed in the treatment of idiots. Among the more purely scientific articles is one upon the question of alcoholism in the production of idiocy and epilepsy. Bourneville analyzes 2,554 cases. He finds that conception probably occurred during drunkenness in eighty-six patients, and that 41.1 per cent. of the parents of idiots were alcoholic. (*Verb. sup*). In another chapter Bourneville establishes the fact that thymus disappears rather more rapidly in epileptic idiots than in other forms.

The book contains a number of other interesting articles bearing upon the pathology and etiology of idiocy. Altogether these volumes of Bourneville seem to us to increase in importance and interest as the years go by.

Taschenbuch der Massage, für Studirende und Ärzte. Von Dr. Erich Ekgren. Mit einem Vorwort von Geh. Med.-Rath Prof. Dr. H. Senator. Mit elf Abbildungen. Berlin: S. Karger, 1903.

This concise little volume of 90 pages teems with information of the subject it treats. Before discussing massage of the various parts and organs of the body, the writer speaks of the physiology and technique of massage. After the indications for massage of the various parts are given, the position of the patient and the technique of the special operation are described. The contraindications are then mentioned. A list of the newest literature on the subject and a very good index are appended.

De L'Intervention Chirurgicale dans les Néphrites Médicales. Par M. le Dr. Alfred Pousson, Professeur Agrégé, chargé du cours des maladies des voies urinaires à la Faculté de médecine de Bordeaux, Chirurgien des hôpitaux. Paris: A. Maloine, 1902.

Pousson states that his interventions in medical nephritis have been in cases of (*a*) acute toxi-infectious nephritis, and in cases of (*b*) subacute or chronic nephritis, *i. e.* Bright's disease. He reports these cases in all their details, giving careful notes. He also gives a résumé of the cases which he has been able to collect from the literature, and considers the legitimacy of intervention, the choice of operation, and its mode of action.

Directions for Laboratory Work in Physiological Chemistry. For the Use of Students in the University and Bellevue Hospital Medical College. By Holmes C. Jackson, Ph.D., Instructor in Physiological Chemistry. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1902.

This book is intended especially as a guide to students in Physiological Chemistry. Blank pages are inserted throughout the volume for the student's notes. The various subjects are briefly but clearly treated. Among these are: General proteids, fats, carbohydrates, bone, saliva, gastric, and pancreatic digestion, bile, blood, milk, urine, quantitative determinations, pathological constituents, and sediments.

Obstinate Hiccough. By L. F. B. Knuthsen, M.D. Edin. London: J. & A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1902.

The author has not only reported one case of obstinate hiccough occurring in his own practice, but has collected over 150 other cases. The book is divided into six sections, four of which contain abstracts of reported cases which have appeared in British and foreign medical journals, as well as in textbooks and various reviews. The fifth section treats of the anatomy, physiology, and pathology of the affection, while the sixth considers the treatment. The author is of the opinion that the most scholarly and classical article that has appeared on the subject is the one published by Dr. W. Langford Symes in 1893. He adopts that writer's classification of hiccough into four types, viz.: (1) The inflammatory; (2) the irritative; (3) the specific, and (4) the neurotic. In the first, the hiccough is attributed to a congested state of the stomach and bowel; in the second it arises from distention of the stomach or irritation, produced by worms, dyspepsia, dentition, pressure on nerve trunks, and the passing of catheters and bougies; in the third type there is thought to be an underlying constitutional condition, such as malaria or gout. A number of authorities are of the opinion that the neurotic type is a modified form of epilepsy. The treatment of hiccough is necessarily disappointing, but it has been made in this book as rational as possible by founding it upon the classification already given. In addition, there is presented, in tabular form, the drugs and methods which have proved successful in the reported cases. This study shows the gouty form to be very intractable, and one of the most fatal.

The Story of a Living Temple. By Frederick M. Rossiter, B.S., M.D., and Mary Henry Rossiter, A.M. Chicago, New York, and Toronto: Fleming H. Revell Co., 1902.

The avowed object of this book is to arouse a deeper interest in the study of the human body by presenting practical physiology and hygiene in a form which is at once popular and fascinating. In this the authors have succeeded very well. The "living temple" is, of course, the human body. This analogy is carefully maintained throughout, and becomes at times quite fanciful, as in a portion of the description of the "antechambers" of the temple, viz., "To meet the blood the air must pass through a hall, a vestibule, a music room, and a corridor." The descriptions of the organs of hearing, and of the processes of digestion and absorption are especially good. Under the head of "good building materials" are some sensible remarks on dietetics, but there is evidently a strong leaning toward vegetarianism, and the scientific mind is not pleasantly impressed by the repeated references to alcohol, tea, coffee, and tobacco as "the thieves and murderers" of the temple.

A Manual of Dissection and Practical Anatomy Founded on Gray and Gerrish. By William T. Eckley, M.D., Professor of Anatomy in the Medical and Dental Departments of the University of Illinois, etc., and Corinne B. Eckley, Demonstrator of Anatomy in the Medical and Dental Departments of the University of Illinois, etc. Illustrated with 220 engravings, 116 of which are colored. Philadelphia and New York: Lea Brothers & Co., 1902.

This manual has been compiled by selections from two standard works on anatomy, the authors having selected what appears to them most useful for a work of this kind. The illustrations have been carefully reproduced, and enough descriptive text accompanies them to serve the purpose. We think that there is undoubtedly a place for this book, which takes the place of the larger work of reference, and which, at the same time, is a useful laboratory guide. It possesses the advantages of a quiz-compend, without the disadvantages dependent on incompleteness, which is seen in such works.

Diseases of the Pancreas and Their Surgical Treatment. By A. W. Mayo Robson, F.R.C.S., Senior Surgeon, Leeds General Infirmary, Emeritus Professor of Surgery, Yorkshire College, Victoria University, etc., and B. G. A Moynihan, M.S. (Lond.), F.R.C.S., Assistant Surgeon Leeds Infirmary; Consulting Surgeon to the Skipton Hospital, etc. Illustrated. Philadelphia and London: W. B. Saunders & Company, 1903.

The authors of this volume have previously published the results of their experiences in other departments of abdominal surgery than that which is now under consideration, and their reputation for accuracy and progressiveness has been established. Until the past few years, the diseases of the pancreas have been wrapped in more or less obscurity, both on account of insufficient pathological information and also on account of the indefiniteness and irregularity of the clinical pictures with which we are confronted. An attempt has been made in this book to systematize our present information and to add to it from personal experience and from material collected from recent medical literature. Much painstaking effort has evidently been expended in the way of bibliographical references, and the result leaves little to be desired. All pathological conditions of the organ are described, and their significance fully discussed, with many clinical reports and references introduced into the text, but most attention is devoted to inflammatory conditions, that very interesting condition, acute pancreatitis, receiving a large share. We are impressed with the remarkable nature of the latter condition, the difficulties of diagnosis, and the unsatisfactory nature of our means of treatment, which are practically those of acute peritonitis. Many clinical references are given, and some interesting pathological deductions are made. Other subjects treated *in extenso* are subacute pancreatitis, cystic formations, and new growths of various kinds, with special attention to carcinoma.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Jan. 1, 1903.

Foot-and-Mouth Disease.—Langdon Frothingham describes epizoötic aphtha as an acute, infectious, exanthematous disease peculiar to cloven-footed animals, both wild and domestic. It has often been observed in man, especially when exposure has been great, as in persons caring for sick animals, inmates of a cloister constantly drinking infected milk, in children feeding upon raw milk from diseased cows, etc. On the second day after infection rather severe constitutional symptoms appear, with fever, headache, nausea, and ptyalism, and soon thereafter eruptions in the mouth and upon the cheeks. The disease is seldom fatal in man. The cause of foot-and-mouth disease is assumed to be a bacterium, but the true nature of the contagion still remains unknown. In spite of many difficulties in the way, Loeffler is still continuing investigations, with the view of discovering an immunizing serum. With the cow he has not as yet been successful, but with sheep and swine better results have been obtained.

Note on Multiple Primary Tumors.—Paul G. Woolley calls attention to the fact that the common conception of a primary focus of growth in the case of malignant tumors is far from having an absolutely demonstrated foundation; that when we are apparently dealing with a single primary focus, we often have (as Peterson has shown) multiple foci; that there are not infrequent cases in which it would seem as probable, or more probable, that what we are dealing with is not extension through a tissue or organ, or system, but the independent development of new growths, of like histological characters, malignant as well as benign, at separated points—and this presumably under the influence of a common affection at the different points—and that there are very many cases on record in which there has been the simultaneous presence and growth of neoplasms of very different orders. The author reports a case of his own, and gives a list of collected cases which bear out his view. He begs observers to watch for cases of multiple primary growths, and record with them careful studies of the general conditions, as well as of the special ones surrounding the patients. Such records in cases of tumors in paired organs, such as the breasts, adrenals, ovaries, etc., would be of the greatest interest and value in determining whether metastasis or biological change is the more obvious factor in the production of such cases.

Chloride of Ethyl as a General Anæsthetic.—Charles Greene Cumston holds that this anæsthetic may be given to subjects of any age, principally at the two extremes of life. In examinations requiring a general anæsthetic there is nothing that can compare with it, and for short operations, such as arthrotomy, the opening of an abscess, deep cauterizations, curettement of the uterus, the reduction of certain dislocations and fractures, etc., it is ideal. Throat specialists also will find it of great value. On account of the facility with which it is given and its harmlessness, an experienced anæsthetist is not required, and it may be given by any careful physician. These are the principal advantages which it presents for operations of short duration, not lasting over four or five minutes. When used as a preliminary to the administration of ether, it avoids the period of excitement, and on account of its pleasant odor and non-stifling effect the most nervous patient will take it with ease. The amount of ether used afterward may be safely put at one-third to one-half less than would have been required had the anæsthesia been entirely with ether. The transition from one anæsthetic to the other is quite insensible. Operative shock has been greatly diminished in the major operations done by the author, when chloride of ethyl has been used as a preliminary anæsthetic, and nausea has been absent in almost all of them when consciousness has returned.

Journal of the American Medical Association, Jan. 3, 1903.

Uncinariasis or Ankylostomiasis.—A fatal case of this nature is described by J. A. Capps, who gives a full account of the life history of the parasite, and a synopsis of previously reported cases. The symptoms of the malady fall into two general groups, viz., those of pastrointestinal irritation, and those arising from anæmia of varying intensity. In making a diagnosis of a doubtful case, we are to note the occupation of the patient (workers in dirt, clay, mines, canals, etc., camp life, farmers, and, in general, those exposed to insanitary conditions), the condition of the blood (resembling pernicious anæmia), and finally the possible presence of the hook-worms in the fæces. This last is the positive test. The malady is curable if recognized early and treated promptly. The bowels should be cleared the evening before administering the anthelmintic. Thymol in a 2-gram dose, repeated in two hours, and followed by a saline is effective, as a rule. Santonin and male fern are not so satisfactory. Prevention can be best accomplished by: (1) Drainage and drying of swampy lands. (2) Where numbers of men are working in tunnels, ditches or canals, by examination of the fæces of workmen, and the exclusion of infected individuals. (3) Proper disposal of dejecta in suspected localities by burning or by disinfectants. (4) Enforcement of cleanliness in washing the hands before taking food. (5) A pure water supply.

A Contribution to the Subject of Radiotherapy and Phototherapy in Carcinoma, Tuberculosis, and Other Diseases of the Skin.—J. N. Hyde and O. S. Ormsby present, in a paper elaborately illustrated, their experience with radiotherapy and phototherapy in carcinoma, tuberculosis, psoriasis, hypertrichosis, alopecia areata, ringworm, acne rosacea, sycosis, keloid scars, chronic eczema, and mycosis fungoides. Their experience leads them to believe that in tuberculosis of the skin these methods of treatment are superior to any others now known. In lupus erythematosus, phototherapy has in their hands given very satisfactory results, far better than those they had obtained by any other method. In superficial carcinoma, involving considerable areas, radiotherapy is undoubtedly preferable to all other known methods of treatment. Superficial lesions more circumscribed, are equally amenable to treatment with the *x*-rays, though, in many instances, small tumors can be removed more promptly by complete erasion or incision. For many of these circumscribed growths they advocate removal either with the knife or curette, followed by a series of treatments with the *x*-rays. In operable carcinoma of the skin, which includes deeper tissues, they advocate complete extirpation, followed by *x*-ray treatments. Where the growths are inoperable, radiotherapy offers a possible chance of recovery, or of lessening the discomfort of the patient. As a result, however, of their observations of their own and other cases, they believe that in exciting an inflammation in carcinoma one is, to some extent at least, encouraging an extension of the growth through a dissemination of the cancer-cells to normal (or inflamed) tissue, surrounding the growth, and of favoring metastases. They believe this possibility constitutes a danger in the treatment of carcinoma by the *x*-rays that has not been sufficiently recognized. It is not yet possible to draw definite conclusions, with reference to the comparative values of radiotherapy and phototherapy. The former is, for the most part, readier of application, and, apparently, has a wider field of usefulness than the latter. In lupus erythematosus, however, phototherapy has repeatedly given excellent results where the *x*-rays have failed altogether, or aggravated the condition. Judging from their own experience, and from the larger experience of Finsen, and others, in the treatment of tuberculosis of the skin, they believe that in this disease phototherapy gives in the end, results as rapid as those obtained with the *x*-rays, with better cosmetic effects, and without danger of deep burns.

Medical News, January 3, 1903.

Why Chloroform Should Be Used in Puerperal Eclampsia.—Douglas H. Stewart declares that sugar is an antiseptic. It is the general opinion that the alkaline reaction in decomposing urine is due to the production of carbonate of ammonia. One of the many elements in the toxæmia of puerperal eclampsia is the changing of urea into ammonium carbonate. This salt is the result of the principal change in that complex blood poisoning which gives rise to the characteristic convulsions. Chloroform produces a temporary glycosuria. If we admit the presence of sugar in the blood, it can be demonstrated in the test tube that it does prevent the changing of urea into ammonium carbonate. It would seem then that chloroform with its accompanying glycosuria is the test anæsthetic in puerperal convulsions, not that it will inhibit the development of all the poisons in the toxæmia, but it will limit the production of the chief one.

The Diuretic Action of Rectal Irrigation; the Specific Action of Normal Saline Solution in the Production of Diuresis.—Robert Coleman Kemp calls attention to the fact that normal, or rather deci-normal, saline solution, has a specific effect on the kidney cells, in promoting diuresis, and this occurs, whether the solution is administered by infusion, by hypodermoclysis, or by enteroclysis. It occurs, even when such small quantities are employed, that the attached mercurial manometer demonstrates no increase in arterial tension. It takes place even when the renal nerves are sundered. Normal saline solution will diminish acute renal congestion. The writer has often seen profuse diuresis and the gradual disappearance of albumin, casts, and blood, the increase of urine commencing in twenty minutes (the interval of absorption).

The double current irrigation is employed. Rubber sheeting protects the bed, and the bedpan is not used. The water is drained by a carry-off tube into a pail. The outflow tube must be pinched, so that the fluid will pass up into the bowel. From three to twelve gallons are used at a sitting. The irrigations may be given every two to three hours, if necessary, in severe cases. As to temperature, the writer advocates continual enteroclysis at 110° F., gradually increasing to 120° F. He concludes that with frequent small venesections, combined with properly administered irrigations, the scale may be turned in the patient's favor in half an hour. He suggests that an infusion of normal saline solution at 120° F., given at the site of the venesection, might prove of the greatest value.

New York Medical Journal, January 3, 1903.

The Diagnostic Value of Abdominal Rigidity.—J. A. Blake says that abdominal rigidity is a constant symptom in all irritations and inflammations of the peritoneum, and is, therefore, a valuable sign in the diagnosis of the presence of foreign materials in the peritoneal cavity, even before inflammation has ensued. It is a fairly accurate index to the severity and extent of a peritoneal implication, and is, therefore, valuable in observing the course and estimating the severity of a peritonitis. It is a more reliable sign than pain or tenderness in the diagnosis of perforation occurring in typhoid fever. On the other hand, we must remember that the determination of rigidity in the upper part of the abdomen is not always easy, and that it may be present in inflammation of the pleura, the peritoneum being normal.

Bronchial Phthisis.—A. Abrams refers to the common definition of this malady as a tuberculous lymphadenitis of the tracheobronchial glands, but believes that there is a type of the disease not so much characterized by pressure symptoms as presenting a clinical picture similar to that of ordinary pulmonary tuberculosis. The gland process may end variously. They may (1) heal spontaneously; that is to say, the tuberculous process may remain dormant for years; (2) may undergo suppuration, probably the result of mixed infection with pyogenic organisms; (3) may perforate the vessels and lead to systemic infection; (4) may suppurate and perforate the œsophagus or bronchus. When they perforate the bronchus, the symptomatic picture may be essentially that of pulmonary tuberculosis, and it is to this picture that the twenty-five cases collected by the writer refer. The main symptoms may be summarized as follows: (1) Mucopurulent sputum containing tubercle bacilli; (2) dyspnœa; (3) hæmoptysis; (4) pyrexia; (5) paroxysmal, spasmodic cough; (6) percussion signs; (7) auscultatory signs; (8) pressure signs, and (9) Röntgen ray evidence. The only remedy mentioned by the author (outside of the usual therapy) is inunctions of one drachm daily of sapo viridis rubbed in daily in different portions of the body.

The Present Status of Treatment of Hypertrophy of the Prostate.—N. P. Dandridge urges that we should not be carried away by the operative furor of the present time, but we should remember that the older methods still possess a large field of usefulness. There are, indeed, many cases in which surgery alone will relieve the obstructed urinary flow and cure the cystitis. In a certain number of cases complete relief will follow simple perineal incision with drainage for some weeks. It is in the large remainder that perineal prostatectomy promises a large field of usefulness. It must not be postponed too late or a large percentage of mortality will certainly ensue. It must be looked upon as a grave surgical procedure involving a considerable loss of blood, a notable laceration of tissue, and requiring a somewhat prolonged anæsthesia, all conditions badly borne by this class of persons. That it is possible effective experience already shows; whether, however, permanent immunity will be secured from a progressive cystitis and further involvement of the kidneys remains to be seen, and whether many of those operated on between sixty and seventy will reach the age of eighty is something yet to be determined. The operation of complete perineal prostatectomy is still of too recent date to allow of positive deductions as to the permanency of the results it offers.

American Medicine, January 3, 1903.

The Etiology of Uterine and Pelvic Disease.—Clarence L. Wheaton recognizes indiscretions at the menstrual period as a prolific source of uterine disease in young girls who have reached puberty. Another cause of these troubles is imprudence while the uterus is in process of involution. Absolute rest during the process of involution would seem indicated. In applying a bandage to the abdomen, the uterus must not be forced down into the pelvis. Tears of the perineum must be properly attended to. Gonorrhœa is a fertile cause of endometritis and of tubal disease. The crimes of the abortionist are a prolific source of uterine and pelvic disease.

Some of the Surgical Uses of Clove Oil.—W. A. Briggs advocates the application of clove oil to the hands and arms after they have been washed with soap and water, preparatory to operating. The rubber gloves are put on without removing the oil from the skin. After cleansing the operative field with soap and water, a mixture of equal parts of clove oil and lanolin is applied, and later the pure oil. This application is removed by ether. The writer considers clove oil a positive, non-irritant, and continuous antiseptic, and finds it most useful in the treatment of infected wounds. He often packs abscess cavities with gauze saturated with the pure clove oil. He uses this oil as a hand disinfectant in obstetric cases. He also uses it as a dressing for the umbilical cord. The oil is practically non-toxic. Locally, it is distinctly analgesic and powerfully antiseptic.

Two Examples of Parasitic Hæmaturia.—L. Napoleon Boston reports these cases. The first patient was a man sixty-one years old. On rising one morning he noticed that his urine resembled blood. There was no discomfort. There were a few parasites found. Dr. Stiles of Washington, who examined several of the parasites, reported that he was unable to make a specific or even a generic determination. The size of the worm seemed to disagree with the embryos of filaria bancrofti. One trichocephalus egg was found in one of the specimens. The second case was one of hæmaturia, resulting from the development of an echinococcic cyst, whose products were eliminated through the urine. The urine was blood-stained and showed a heavy sediment, composed, for the most part, of shreds of flocculent membrane. There were hooklets and scolices of the tænia echinococcus and many blood-casts present.

Philadelphia Medical Journal, January 3, 1903.

A Case of Traumatic Rupture of the Bladder; Recovery.—Edward A. Schumann describes the case of a man, aged forty-one years, with a history of absolute retention of urine for thirty-six hours, and a vague history of having been run over. Upon the injection of 100 c.c. of boric acid solution into the bladder, none returned through the catheter, and a diagnosis of traumatic rupture of the bladder was made. Operation revealed an area of necrosis in the anterior vesical wall with a rent in its center. The bladder was drained by a glass tube introduced through the rent. The wound was packed and permanent drainage maintained by means of a siphon drain, which kept the bladder always empty. Ten weeks after the operation the patient was voiding the major part of the urine normally, only a few drops escaping through the sinus in the abdominal wall. He has gained in weight and strength.

The Perineum.—James D. Love believes that practically all unrepaired perineal injuries are attended sooner or later by a certain definite train of symptoms. The perineal injury is intimately related to uterine subinvolution, metritis, endometritis, uterine retrodisplacement, and prolapse. Perineal injury can be avoided in a large percentage of cases if the etiology of the lesions is carefully borne in mind and all needful precautions observed. The most frequent etiological factor is the rapid delivery of the child's head with forceps. Another, is faulty position on the part of the mother. The writer delivers all primiparæ, at least, in the left lateral prone position. It is now admitted that every case of perineal laceration demands immediate repair when this is possible. The writer does not employ the vaginal douche in these cases. He binds the knees of the patient together and enforces the dorsal position. He believes that Kelly's modification of Emmet's operation will almost invariably furnish the patient with a perineum restored to its former function.

A Local Electric Light Bath.—C. C. F. Nieschang states that the electric light possesses properties identical with those of the sun's rays. In the arc-light the luminous and chemical rays predominate, but in the incandescent light the heat-rays are in the ascendency. The incandescent light has also a superior heating quality. It is very effective in the relief of pain, painful joint affections, neuralgia, etc. It has a decided advantage over the superheated or hot-air apparatus, as the rays penetrate the tissues deeply and are readily transformed into heat in the deeper layers. The therapeutic effect is due to the peculiar activity and influence of the thermal and actinic rays on the tissue metabolism. The writer describes a simple instrument which he uses, consisting of an insulated cone, lined with abestos sheeting. The edges of the cone are protected by a rubber cushion. It has a handle, connecting cord, plug, and lamp. It is portable. It can be used instead of poultices for abscesses, boils, carbuncles, etc. By wringing

out flannel in hot water and applying it to the parts over which the apparatus is placed its power is increased.

The Lancet, December 20, 1902.

Volvulus of the Small Intestine.—A case of this rare condition is reported by A. H. Burgess, whose patient was a boy of eight years, who was suddenly seized with violent abdominal pain and symptoms of intestinal obstruction, and died in sixteen hours after the onset of symptoms. Autopsy revealed the fact that the whole of the jejunum and ileum, together with the cæcum and commencement of the ascending colon, constituted a volvulus, the pedicle of which was formed by the intertwining of the beginning of the jejunum with the middle of the ascending colon. The small gut, cæcum, and lower portion of the ascending colon possessed a common mesentery, which, while of considerable depth as measured from its spinal to its mesenteric attachments, was of very limited vertical extent, so that the commencement of the jejunum and the middle of the ascending colon were closely approximated.

The Treatment of Diphtheria by the Intravenous Administration of Anti-diphtheritic Serum.—D. L. Cairns was led to try this method of antitoxin administration in that type of the disease characterized by the extension of the morbid deposit to the bronchioles with its large mortality rate. He gives the detailed histories of seven cases, all recovering. The intravenous dose ranged from 20,000 to 35,000 units. No untoward results beyond the usual serum rash and some pyrexia were observed. Very noticeable were: (1) The rapid disappearance of the general toxæmia; (2) the rapid disappearance of glandular enlargement, and (3) the marked diminution of the restlessness in the pneumonic cases. He would lay down as the general indications for this mode of therapy the following: (1) Malignant diphtheria, *i. e.* with nasal or skin hemorrhages, great glandular enlargement, marked cellular infiltration and extreme blanching of the skin; (2) any marked involvement, of the lungs, either when the case is first seen or subsequently; (3) a moribund condition of the patient, and (4) a profound toxæmia.

Congenital Hypertrophic Stenosis of the Pylorus and Its Treatment by Pyloroplasty.—E. Cantley and C. T. Dent gave a brief synopsis of seven personal cases of this condition and analyzed them together with a larger number of cases previously reported. Their main ideas are: (1) That the condition is probably far more common than is generally believed; (2) that it is still not generally recognized, for the symptoms may easily misunderstood or overlooked; and (3) that it may be successfully treated by pyloroplasty. The causation of the condition is still uncertain. Some refer it to a primary hyperplasia of the muscular tissue, an overgrowth due to a fault in development; others believe that the hypertrophy is secondary and results from over-exertion of the muscle, this being due to functional disturbance of the nervous mechanism of the stomach and pylorus. If the condition be due to pyloric spasm, in all cases the affection should be amenable to treatment short of operation; and the fact that medical treatment in marked cases has hitherto proved futile should not deter us from seeking for more efficient remedies than have hitherto been found. As in the view of the authors the condition is more probably due to a muscular hypertrophy which is not the result of spasm, they hold that while surgical measures are imperatively demanded in the strongly marked cases, they may also be with advantage adopted even in slight degrees of the affection. Undue delay, especially in cases that are not of the severest type, is likely to lead to dilatation of the stomach; and when the stomach is much dilated the results of operation of any kind are far less likely to be good. The food may be able to get out of the stomach, but it will not be properly assimilated.

The Lancet, December 27, 1902.

Operation for Chronic Ulcer of the Stomach.—C. W. Mansell Moullin discusses the general status of this operation, with its indications and technical features. His article is of interest, as giving his personal experience. Taking acute and chronic cases together, he has operated by either excision or ligature, thirteen times (cases in which perforation had occurred being excluded). In many of them the loss of blood had already been extreme. In six transfusion had to be performed on the table, or immediately after. Two of these patients, both of whom were in an absolutely desperate condition at the time of the operation, died: the rest recovered without a bad symptom, and were cured. He cannot help thinking that if these two had been operated upon before they had lost so much blood, they would have stood as good a chance of recovery as the others, and he feels convinced that if only ulcers of the stomach were operated upon as soon as it was recognized, that they had become chronic, there would be many fewer deaths from hæmatemesis and perforation, and that such troubles as pyloric stenosis, hour-glass contraction, pain, and dyspepsia from adhesions, perigastric and subphrenic abscesses, and dilatation of the stomach would become far more rare than they are now

The Prevention of Typhoid Fever in Armies.—H. E. Leigh Canney reviews our knowledge concerning the nature and modes of transmission of typhoid fever, and draws certain lessons from various recent wars all over the world. His main proposition relates to the use of "protected" water, by which he refers, in a general way, to water purified either chemically, by filtration or by boiling. His conclusions are as follows: (1) That unless all the water avenues to an army or camp have been protected, it cannot be assumed that the incidence of typhoid fever is due to air-borne agencies. (2) That it is not possible to affirm that the water avenues to an army are closed, unless the sterilization and distribution of the water are carried out by specially trained men. (3) That the evidence of air-borne typhoid fever is not clearly established in recorded Indian military experience. (4) That in South Africa and Egypt the evidence is opposed to this theory. (5) That the weight of evidence from India, Egypt, and South Africa is immensely in favor of the paramount importance of the water avenues, especially in the onset of epidemics, and that the spread of the disease by the subsidiary avenues, flies, dust, and contact, only becomes a factor of importance under conditions of the grossest neglect of sanitation. (6) The evidence from Egypt proves that if the water avenues are protected all other avenues are powerless to originate and to spread *epidemics* of typhoid fever in large bodies of men.

Reflexes; Their Relation to Diagnosis in Rheumatoid Arthritis.—In a study of the asymmetrical cases of rheumatoid arthritis, H. L. Jones finds that the deep reflexes on the affected side are much more active than on the other. The superficial reflexes, on the other hand, show much less uniformity in their behavior. They may be exaggerated or be very sluggish. The scapular reflex, for instance, may, on the stroking of the skin, respond vigorously, or the reverse, but the tendon reflexes, *i. e.* biceps, triceps, etc., are always accentuated. The uniform increase in the deep reflexes sharply contrasts itself with the variability of the superficial, and in an attempt at explanation the author states can only say that, although when disease is confined to the knee-joint, the plantar reflex is usually of high grade; on the other hand, sluggishness of the plantar reflex only occurs when the ankle-joint is either coincidently or independently the seat of disease. Again, usually in these cases there are coldness and blueness of the feet, with profuse plantar sweating, and the joint mischief is actively progressive. On the other hand, should many months intervene between the affection of the knee and ankle, the mischief in the latter joint may have undergone a partial or complete resolution, the swelling and pain and plantar sweating, etc., have disappeared, and the skin, unnaturally dry and harsh in many of these chronic forms, responds vigorously to tickling. The exaggeration of the plantar reflexes, when present, may reach a high grade, and, in some cases, shows a tendency to spread to the opposite limb, whose tensor vaginæ femoris will be seen to contract vigorously, but the author was not able to evoke a bilateral reflex by stimulating the sole of an unaffected limb. He has, in a few cases, seen a definite extensor reaction in response to plantar stimulation (Babinski's sign). The author believes that there is strong evidence of the truth of the infective theory of the disease, but finds no specific morbid agent. Toxæmia from any source of autointoxication may, through its action on the cord segments, produce what is called rheumatoid arthritis. Imperfect convalescence, also, after many diseases, some of them avowedly infective, may provide the soil on which the rheumatoid affection is nurtured.

British Medical Journal, December 20, 1902

A Case of Spontaneous Disappearance of a Recurrent Mammary Carcinoma.—Reginald J. Willson describes this patient, who was a woman, aged forty-eight years, and single. In March, 1895, she was operated on for cancer of the left breast. Four years ago, and again two years ago, she had recurrences removed. About the middle of July, 1901, she was examined, but with difficulty, on account of extreme pain. There were numerous red hard nodules all around the scar. At the end of July she became distinctly melancholic and refused further injections of morphine. Although up to this time her menses had been regular, they stopped at this time and have never returned. By November the nodules had quite disappeared. In the following June she was removed to the asylum, as she was becoming violent. She eats ravenously almost continuously, but remains very thin. Since the abnormal mental condition has supervened pain has ceased. The

menopause and cessation of pain were synchronous, the melancholia and disappearance of cancer nodules following almost immediately.

Unrecognized Influenza.—J. W. Washbourn and J. W. H. Eyre declare that influenza often escapes recognition, not only in the mild cases but even in the fatal ones. In their study of bronchopneumonia, they have examined the lungs from twelve cases, from four of which they have isolated and identified the B. influenzæ. In four others they have observed bacilli which were morphologically identical with the B. influenzæ, but which were not subjected to the tests necessary to establish their absolute identity. It is of interest to note that in two of the cases the intraperitoneal injection of material containing the B. influenzæ was followed by death in about forty-eight hours from septicæmia, and the influenza bacillus was obtained direct from the heart blood, in one case associated with staphylococcus albus, from which it was easily separated; in the other in a state of purity. Its presence was also demonstrated microscopically in smear preparations from the spleen pulp. On the other hand, intraperitoneal inoculation of even large doses of early generations of the bacillus influenzæ subcultivated upon blood agar failed to induce general infection and death.

Serum Reaction of Bacillus Pestis in Plague.—R. Row deduces the following facts from his experiments in this work: (1) Serum of plague convalescents is remarkable for its bactericidal property to bacillus pestis. This property has been observed in convalescents of over six weeks, and has been maintained, though to a less extent, in two cases of plague patients who had plague twelve and eighteen months ago respectively, and whose blood has just been examined again. The growth is absent; involution forms are constantly found. (2) The serum of patients in the very early stages of the disease is certainly inhibitory to the growth of bacillus pestis. The bacilli are few and far between, found only on "hunting," and involution forms are constantly found. (3) The serum of blood from normal individuals gives very good growths, generally speaking. There are some individuals who give a scantier growth than others, but not one instance has been found in which the blood has completely destroyed the growth. The practical value of these observations is of doubtful nature from a clinical point of view, for the features of the disease develop with such rapidity that no doubt of the nature of the disease is left, while the observation takes at least twenty hours to give a decided opinion. But its application seems to give ample scope to work out various problems connected with the subject.

British Medical Journal, December 27, 1902.

Case of Hyperpyrexia after Influenza.—F. Harman Brown attended a woman of twenty-six years with an attack of influenza. She was progressing favorably, but about a week later her temperature began to rise. A soft blowing systolic murmur developed. About two weeks after the beginning of the illness she became much worse. Coma developed, with stertorous breathing and contracted pupils. The axillary temperature was 110° F. She was pulseless at the wrist and the lips were blue. Cold packs were applied, but the patient died within an hour. Ten minutes after death the temperature was 110° F.

On the Growth of Bacteria in the Intestine.—J. Lorrain Smith and J. Tennant have made interesting investigations in this subject. They have shown clearly that one of the first places in which a disturbance of the regulation of bacterial growth takes place is the region of the ileocæcal junction. The power of inhibiting bacterial growth having become impaired, the bacteria which occur normally in the large intestine will become still more abundant, and approximately similar changes will take place in the small intestine. In the region of the ileocæcal valve the change will occur to a greater extent than in the higher parts of the small intestine. This conclusion follows from a study of the relatively sterile area in the small intestine seen in cases of dogs infected with parasites. In the human subject the region of the ileocæcal valve is very liable to attacks of inflammation in the shape of appendicitis and typhlitis in their various forms, and it is probable that these diseases afford an illustration of the mode of bacterial increase just described. Further illustrations are the lesions of typhoid fever and tuberculosis of the intestine. Probably bacterial invasion of a specific kind follows in these cases the same law as the simple disturbance of regulation due to such non-specific causes as the writers have investigated.

Two Cases of Obscure Abdominal Pain; Operations; Results.—Eric Pritchard describes these cases. The first was a woman of fifty-three years, who had a very long and anomalous illness. Up to the time of operation, all of the medical men who examined the case thought that they were dealing with one of obstructive jaundice, either simple or complicated. In spite of the most careful examination, however, no calculus had ever been discovered in the stools. The operation showed that there was nothing to suggest that the gall-bladder or bile ducts had contained a number of calculi corresponding to the frequent attacks which had been regarded as biliary colic. Anodynes of the nature of phenacetine had a more complete control of the pain and temperature than had hypodermic injections of morphine. Although within a few weeks of the time of the operation all the symptoms indisputably pointed to an obstructive jaundice, nevertheless, after the urine and fæces had become perfectly normal, the main features of the case showed very little alteration. The remarkable subsidence of symptoms which followed immediately on the operation suggested that a functional nervous disturbance was at the root of the matter. But it is difficult to see how a functional disturbance, without some organic basis, could account for all the symptoms of this illness and a high temperature lasting nearly four months. The second case was that of a woman nearly sixty years of age. She complained of pain in the right epigastric region. At operation, a mass of fairly dense fibrous adhesions was found, connecting the upper part of the duodenum with the right border of the stomach. The duodenum at its junction with the stomach was kinked at rather an acute angle. The adhesions were released. The patient made an excellent recovery, and for about two months was almost completely free from pain. But about four months after operation the pain became again practically as severe as before. Later, improvement began to take place.

Münchener medicinische Wochenschrift, December 9, 1902.

Operative Treatment of Perforations of the Gall-bladder.—L. Baldassari and A. Gardini think that perforations of the gall-bladder are best remedied by the transplantation of a serosa-muscular flap, taken from the abdominal wall, in the vicinity of the laparotomy incision. Various experimenters have used the omentum for transplantation purposes, and have obtained, apparently, very fair results. The chief objection to this method is its lack of durability, on account of the thinness and delicacy of the omentum. Such a serosa-muscular flap, as above recommended, is much thicker and firmer than the omentum, and its use insures the permanency of the results obtained. The observations of the authors were carried on exclusively upon dogs, and the most rigid antisepsis was observed during the operations.

Diagnostic Value of the Leucocyte Count in Typhoid Fever and Surgical Suppurative Processes.—A. Kühn believes that the hypoleucocytosis (leucopenia) of typhoid fever is one of the most valuable signs in the early diagnosis of this disease. A critical examination of thirty-eight cases showed that it was present in varying degree, in all but three cases, and that it occurred before the appearance of other typical symptoms, such as the Widal-reaction, Diazo-reaction, roseola, enlarged spleen, etc. It should be remembered, however, that low leucocyte counts are obtained in suppurative processes and miliary tuberculosis, so that certain caution should be observed in interpreting low counts, whenever suspicion of the existence of either of these latter diseases is present. An examination of thirty-three acute suppurative processes shows that in such a hyperleucocytosis is always present. The figures increase in direct ratio as the process advances, and if localization takes place the number of leucocytes immediately falls. The grade of the hyperleucocytosis depends, in a certain measure, upon the species of the infecting microorganism, and the resistency of the infected individual.

Munchener medicinische Wochenschrift, December 16, 1902.

Mast Cells versus Clasmatocytes. Ludwig Schreibe believes that Ranvier's clasmatocytes and Ehrlich's mast cells are identical. Ranvier in fixing his preparations used Flemming's mixture, the osmic acid of which, as Schreiber has shown, destroys the basophilic granules of the mast cells. In this manner Ranvier demonstrated the presence of his so-called clasmatocytes which Schreiber regards as none other than mast cells in which the basophilic granules have been damaged by osmic acid. Other observers who have observed cells similar to clasmatocytes have invariably used fixatives which contained osmic acid; thus Maximow in the demonstration of his so-called "polyblasts." It is certain that the presence of typical mast cells can never be demonstrated if the fixing mixtures contain osmic acid in any appreciable amount.

Society Reports.

WESTERN SURGICAL AND GYNECOLOGICAL SOCIETY.

Proceedings of the Twelfth Annual Meeting, Held at St. Joseph, Mo., December 29, and 30, 1902.

FIRST DAY—MORNING SESSION.

The association met in the Commercial Club rooms, under the Presidency of Dr James E. Moore of Minneapolis, Minn.

Address of Welcome.—This was delivered by Jacob Geiger of St. Joseph, Mo., which was responded to by the President.

Evolution of the Treatment of Cancer of the Rectum.—Dr. C. H. Mayo of Rochester, Minn., read a paper on this subject, in which he said that certain definite results were desired in operations for cancer of the rectum, namely, permanent cure, low operative mortality, and a controllable anus, or its best substitute. These results were modified by location, stage of progress, and by the age and condition of the patient. Previous to 1870 operative treatment was almost limited to palliation and lumbar colostomy. From 1870 to 1880 there was a marked advance in all surgery. Drainage methods were developed. Kocher exposed the rectum by the removal of the coccyx, and several perineal operations were advocated. From 1880 to 1890 the development of the germ theory revolutionized surgery, and this period was marked by antisepsis and drainage. More extensive perineal and vaginal operations were advocated, and Kraske made his great advance by resecting the sacrum. The modern surgical treatment was the block removal of the rectum, glands, and gland tissue from below, in some cases, but more often by a combined abdominal and perineal method. Through an abdominal incision a low section of the sigmoid was made, this portion of the colon being saved as a fecal container, and the cut ends of the bowels inverted and closed by a circular suture, rendering the remainder of the operation aseptic. The rectum was separated laterally and below by a peritoneal incision, and pushed down with the glands and fat by blunt dissection, the separation being carried as low as possible beneath the bladder, the remainder of its removal being completed through the perineum. The sigmoid was freed sufficiently to bring the cut end out of an inguinal McBurney muscle separation opening, the skin incision of which was one and one-half inches to one side, and to which the end of the sigmoid was sutured. The bowel was also sutured within the abdomen, to prevent prolapse, and a pad compression of the skin over the sigmoid loop gave a fairly controllable anus.

To sum up the main objections of the past, the author said we had: (1) Ineffectual removal with local recurrence, so common in the perineal type. (2) The extensive mutilating character of the Kraske, before operative conditions were known. (3) The frequent failure of all methods of union of proximal and distal portions of the bowel, which, when united with the destruction of the levator ani and internal sphincter, and anus saved, represented but one-third of the controlling apparatus of the bowel. (4) The frequent formation of stricture, either cicatricial or cancerous, after operation, necessitating inguinal colostomy. (5) The loss of the fecal container in straightening the sigmoid. That sentiment, and not chance, had proven the main reason for continuing to place an uncontrollable anus in an inaccessible situation. The gain in the combined operation had been in a selection of the operation to the case, radical removal *en masse*, with all glands, fat, and connective tissue, or colostomy for palliation; retention of the sigmoid as a fecal container; the peculiar formation of the anus, giving a fair control in an accessible situation.

Carcinoma Uteri.—Dr. H. C. Crowell of Kansas City, Mo., in a paper on this subject stated that unless very early discovered he believed that nothing was gained by hysterectomy for carcinoma of the cervix. Later operations might avail in carcinoma of the body of the uterus. The diagnosis should be confirmed by the microscope in the hands of a competent pathologist. The uterus must be freely movable, capable of being dragged down to the vulva. If not, it was quite probable that the disease had involved the uterosacral ligaments and adjacent tissue, making an operation of doubtful utility. If the disease was clearly made out by touch, appearance, and clinical history, it was rarely possible to secure a radical cure by hysterectomy, if the fatal termination was not accelerated. In cases well advanced, his individual experience led him to believe that more days or months, as the case might be, were added to the life of the patient than by any attempt at extirpation, by cutting and scraping away the necrotic tissue down to solid tissue, burning that surface with the thermocautery; and treating subsequently by touching the surface occasionally with 4-per-cent. formalin. By this treatment disintegration was retarded, hemorrhage and discharges were checked, enabling the patient to recuperate sometimes to a remarkable degree. Suffering was lessened, and the patient was relieved of the shock and dangers attending more radical procedures. The essayist urged more frequent early examinations of parous women, who should be advised of the expediency of such examinations as a routine safeguard after the age of thirty-six years. These two papers were discussed together.

Dr. M. L. Harris of Chicago pointed out the necessity of making a laparotomy previous to the operation in all cases in which the disease extended high, and the surgeon was not perfectly sure from his examinations that it was limited to the lower part of the bowel. His remarks had reference to the paper of Dr. Mayo. This preliminary laparotomy should be resorted to for three purposes: (1) For examination, in order to determine whether or not the case was operable. (2) To facilitate operation, provided one was necessary. The surgeon could decide if it was a case for complete operation, by the combined method referred to by the essayist. (3) To perform a colostomy if the case was inoperable. He thought colostomy was a very valuable operative procedure in many cases.

Dr. Henry T. Byford of Chicago thought the author of the second paper (Dr. Crowell) was too pessimistic. Dr. Byford narrated the case of a woman upon whom he had operated more than ten years ago for cancer, which had involved the entire cervix. The woman was still alive, and had not had a recurrence of the disease. He mentioned a number of cases of carcinoma of the cervix that had recovered following operation.

Dr. H. D. Niles of Salt Lake City, Utah, said he recently had a case in which he was in doubt as to whether the stricture of the bowel was syphilitic or malignant. He resorted to such measures as were available, and was still in doubt. He thought in such a case it would be wise to do a colostomy, and at the same time explore parts of the bowel. In this case an excellent result was obtained, so far as the sphincter was concerned. The patient had excellent control of the bowels. The gridiron incision, and the advisability of doing a colostomy, when in doubt, were the points in the paper of Dr. Mayo that had impressed him forcibly.

Dr. A. C. Bernays of St. Louis, Mo., stated that he had had the opportunity of seeing Dr. Mayo perform the combined operation he had described. The case was one of hard carcinoma, confined to the last portion of the rectum, about one inch above the sphincter. The operation, as executed by Drs. William J. Mayo and C. H. Mayo, was a beautiful piece of surgery, and anyone who had the opportunity of seeing this operation performed would hereafter resort to it in preference to any other.

Dr. D. S. Fairchild of Clinton, Iowa, stated that after having had some experience in operating for cancer of the rectum by the sacral route, and having had but one per-

manent recovery, he was interested in the combined operation that had been described by the essayist. He was thoroughly convinced that surgeons, after seeing this method of operating, would conclude that it was the procedure which would be adopted hereafter.

Disarticulation of the Hip for Sarcoma of the Femur.—Dr. A. E. Halstead of Chicago read a paper on this subject and reported a case, after which he made extended remarks on the diagnosis and prognosis of sarcoma of the femur.

Dr. B. B. Davis of Omaha, Neb., called attention to elevation of temperature in cases of sarcoma of the femur. Several years ago he had a case of sarcoma of the femur, although his first diagnosis was osteomyelitis of chronic form rather than sarcoma, simply because of the elevation of temperature at the time, but he soon found out his mistake. In consulting standard textbooks, he said no mention was made in regard to elevation of temperature in these cases. It was a symptom which should be remembered.

Dr. John P. Lord of Omaha, Neb., mentioned a case of carcinoma of the neck of the femur. Six or eight months previously, a stationary engineer, forty-five years of age, while pursuing his occupation, sustained a fracture of the neck of the femur from a slight violence. There was a history of alleged rheumatic pains, or sciatica, prior to this time. After the injury the patient was taken to his home, was attended by other physicians, who saw him a number of times, and he was treated for this fracture, so that when Dr. Lord saw him it was too late to do the patient any good, on account of marked cachexia. While in a fleshy individual he thought it would be impossible to differentiate this condition by ordinary manipulative methods, yet, with the aid of the *x*-ray, in cases of fracture sustained from comparatively slight violence, the surgeon might be led to suspect the condition and secure the advantage of an *x*-ray examination to detect the early existence of the disease.

Dr. William Jepson of Sioux City, Iowa, mentioned six cases of sarcoma of the femur, two of which developed at the upper end of the femur. These two cases were not subjected to operative intervention. In four cases the disease involved the lower end of the femur, one of which began directly in the tibia, involving the knee-joint, and then the femur. The other three were of the periosteal type. Three of the four cases were subjected to amputation at the junction of the upper with the middle third. The other one was subjected to primary hip-joint amputation. Of the three subjected to amputation through the thigh two died. In other words, two of the three were subjected to secondary disarticulation of the femur at the hip-joint. One of these two died, also one not subjected to this operation. Out of six cases there were only two living.

Dr. Halstead, in closing the discussion, said he had seen two cases of spontaneous fracture of the humerus with central sarcoma. Pathological fracture was the first evidence. In the case reported of central giant-cell sarcoma, Coley's toxins were used for six months continuously, yet the tumor grew as fast as it did before their use. Patient was also treated by the *x*-ray for six months, without any benefit. In all of his cases of sarcoma the use of Coley's toxins had not been followed by success.

Oblique Inguinal Hernia.—Dr. A. E. Benjamin of Minneapolis, Minn., read a paper with this title. He spoke of the treatment of hernia by the early practitioners, saying it was painful, unsatisfactory, and harmful. The present method of operating for hernia, however, was a notable example of the evolution of surgery. Surgeons had reached a point in hernial operations where a permanent cure was quite certain, still there were too many methods and a larger percentage of relapses than surgeons should have. Some of the causes of imperfect results were pointed out. An operation that was not altogether new, but worthy of consideration, was described by him as follows: "The patient is prepared by having the parts shaved the morning of the operation. In doing so, infected areas or vessels are avoided, which may result, when the shaving is done the previous evening or before the parts have been thoroughly cleansed. The time intervening between the evening and morning of the operation favors a greater multiplication of microorganisms. The bowels are emptied, and subsequently kept free from gas accumulation, which lessens the internal pressure. An ordinary incision for a Bassini operation is made. The aponeurosis of the external oblique is slit up to a point opposite the internal ring. The fibers of the internal oblique and transversalis muscles are divided by blunt dissection, thus opening the inguinal canal. The internal oblique and transversalis muscles are found closely connected. They are not separated, but the aponeurosis of the external oblique is carefully and thoroughly removed from the internal oblique. The lower portion is dissected down to Poupart's ligament, and the transversalis separated from the peritoneum. Such careful dissection and positive identification of structures are an important aid in securing direct apposition and firm union. It corrects all defects of nature in this region. The cord is now raised and silkworm-gut sutures introduced, passing through the skin, Poupart's ligament, internal oblique and transversalis. The loop is made on the lower side of the transversalis. The needle, re-entering the transversalis and internal oblique, passes through the skin to the outer and lower side of the cut near the point of entrance. From three to five sutures are similarly introduced. These sutures pull the internal oblique and transversalis below the shelving edge of Poupart's ligament, and are observed to make a firm barrier against any internal force. The sutures are then tied over rolls of sterilized gauze. The spermatic cord rests upon the internal oblique. The external oblique is then closed over the cord. Interrupted figure-of-eight sutures are introduced, bringing the external oblique in apposition with Poupart's ligament. This also approximates the skin, and the sutures are tied over a roll of sterilized gauze. The sutures are usually left two weeks."

The author drew the following conclusions from this operation: (1) There are no sutures for the tissues to absorb. (2) There is no additional culture media in which infectious microorganisms may grow and cause deep abscesses. (3) There are no buried, non-absorbable sutures left to irritate the tissues and cause further trouble. (4) There is no necrosis from tight sutures, therefore few, if any, stitch abscesses. (5) The gauze rolls act as elastic cushions, which prevent scars from the sutures. (6) The operation completely closes the breach, and makes a firm wall. (7) All sutures, after serving their purpose, are removed, leaving only the natural supports.

FIRST DAY—AFTERNOON SESSION.

Rupture of Gall-bladder or Duct from Vomiting, with Rupture of the Appendix in the Same Patient.—Dr. W. W. Grant of Denver, Col., reported this case. He also reported two recent cases of appendicitis because of the interest connected with drainage and phagocytosis. In connection with these cases, he stated that he was satisfied of having saved lives after peritoneal extravasation by the liberal use of gauze for drainage. In abdominal operations drainage imperilled the integrity of the abdominal wall, thereby predisposing to hernia. It should consequently be dispensed with as soon as possible. But in the enthusiasm for new theories and facts, in a justifiable belief in the efficacy of hyperleucocytosis, he believed it was not wise to discard hastily surgical procedures which had stood the test of abundant experience.

Acute Yellow Atrophy of the Liver.—Dr. Grant closed his paper by reporting a case of acute yellow atrophy of the liver. Whether the condition was primarily a general infectious disease of a rare and unusual nature, or primarily a local infectious disease of the liver, was not known. The suggestion of an intestinal origin had no dis-

tinct foundation. The resemblance to phosphorus poisoning was striking, although differing in important particulars. While the urine of both affections might contain leucin and tyrocin, they were more constant in the former disease. Evidently the disease was rapidly diffused through the circulation, and he stated that future investigations would probably disclose a bacterial origin and nature.

Chronic Pancreatitis and Pancreatic Cyst.—In a paper on this subject, Dr. B. B. Davis of Omaha, Neb. reported two cases, one of pancreatic cyst, the other of chronic pancreatitis, both of which had previously been subjected to exploratory abdominal section, and the diagnosis of malignant disease of the pancreas made. In discussing the etiology of pancreatitis, the author stated that infection was considered the determining factor in most cases, the infection being secondary to gallstones, cholecystitis, gastritis, duodenitis, and zymotic diseases, particularly typhoid fever and influenza. It was thought probable that syphilis, alcoholism, and general arteriosclerosis might also cause a small percentage of the cases. With reference to the diagnosis, great dependence must be placed on the clinical symptoms. Glycosuria, fatty stools, and muscle fibers in the stools, which, theoretically, ought to be diagnostic factors in pancreatic disease, practically were usually found absent. In cases in which glycosuria was present, destruction of the islands of Langerhans had been found to exist. In all cases in which infection was the causative factor, prolonged drainage of the gall-bladder was recommended.

Dr. M. L. Harris emphasized the frequency with which stomach troubles preceded chronic pancreatitis. It was possible that stomach troubles, cases of ulcer of the duodenum, were undoubtedly instances of chronic pancreatitis, and might be the result of infection.

Gunshot Wounds of the Stomach.—A paper with this title was read by Dr. J. W. Andrews of Mankato, Minn. The author reported a case of gunshot wound of the stomach in a boy, eleven years of age, upon whom he had operated. The little patient rallied from the shock and did well for the first three days after the operation, when he began to fail, and died on the eighth day. A post-mortem examination showed that death was due to septic peritonitis. In commenting on this and other cases of gunshot wounds of the stomach, the speaker stated that, since surgeons of international reputation did not agree as to an immediate operation, he preferred to accept that which might seem less conservative, namely, an immediate operation in all cases in which it was reasonably certain that the stomach had been perforated.

Fowler's Position in Abdominal Surgery.—Dr. Van Buren Knott of Sioux City, Ia., contributed a paper with this title. Since this position had been brought to his notice, he had employed it in the treatment of cases of septic peritonitis. He reported five recoveries from diffuse septic peritonitis. These successes were not consecutive, however, no two of them having occurred without an intervening failure. Brief histories of the five successful cases were given, as these were the only instances of diffuse septic peritonitis that had been operated upon successfully by the author. The Fowler position was maintained for twenty-four hours, unless some special reason for continuing it was present. The head of the bed should be raised from eighteen to twenty inches from the floor. He urged those present, who had not employed the Fowler position, to do so, for he believed that it could do no harm, but, in many cases, would prove of much value.

Old Irreducible Dislocations of the Shoulder Joint.—Dr. A. F. Jonas of Omaha, Neb., referred at length to the literature of such cases, and reported seven that had occurred in his own practice. His method of dealing with these dislocations consisted chiefly of (1) manipulation, using the forearm as a lever, rotating outward and inward, abduction and adduction, never forgetting for a moment a possible accident to the axillary vessels and nerves, and the possibility of fracturing the humerus. (2) If this plan failed, the capsule was incised, and all cicatricial tissue was extirpated. All muscular attachments that offered restraint were severed, the axillary vessels were protected with a broad, flat retractor, and the head of the bone was brought into place by means of an elevator, assisted by manipulation and traction. To avoid infecting the wound in this last manœuver, it was advisable to firmly wrap the entire arm and hand with wet sublimate towels. Dry towels were liable to slip and become displaced, making it possible for the operator's hand to become infected. If the head could not be replaced, then (3) the head of the humerus should be resected, an operation to be avoided, when possible, on account of the resultant flail-like condition of the arm, and yet must be done (*a*) when the humeral head and neck became too extensively stripped of their attachments, experience having shown that necrosis might occur in 16 per cent. of the cases; (*b*) when osseous union had occurred between the head and the ribs; (*c*) when, after a division of all restraining soft parts, the head rested against the point of the acromion process.

Case of End-to-End Anastomosis of the Popliteal Artery for Gunshot Injury.—Dr. Alexander Hugh Ferguson of Chicago reported this case. He gave a history of the injury, described the physical findings, and the operation which he performed.

Treatment of Injuries of the Pelvic Floor Occurring During Parturition.—Dr. William E. Ground of West Superior, Wis., read a paper with this title. His conclusions were that almost every woman, during her confinement, suffered injuries from which she did not recover unless she was subjected to a secondary operation for repair of lacerations of the pelvic floor; that immediate suture of apparent lacerations did not restore pelvic support in the vast majority of cases; that from one to two months after labor the woman should be subjected to a thorough examination, and any relaxation corrected before it had time to impair her health.

Lung Surgery; Historical and Experimental.—Dr. B. Merrill Ricketts of Cincinnati, Ohio, presented an elaborate contribution on this subject, which was illustrated by lantern slides. We give the author's conclusions in his own words: (1) Severing one or more of the larger pulmonary blood vessels results in instant death. (2) If death does not result in a few minutes, bleeding will be slow and gradual. (3) If bleeding is slow and gradual, it may require hours or days to cause fatal exhaustion. (4) If death does not occur until after the end of the second day following severe bleeding, infection is the cause. (5) All, or a part, of the escaped blood may pass through the opening in the chest into the bronchus or alimentary tract. (6) The blood may escape into the pleural cavity or cavities, pericardial or peritoneal cavity, or all, and thereby become concealed.

(1) **Pneumonotomy.**—More definite knowledge of conditions and symptomatology is necessary that surgery of the lung may be perfected and made more aggressive in general. (2) Abnormalities, congenital or acquired, must always be considered in dealing surgically with the lungs. (3) Atalectasis and apneumatosis should be cared for by relieving the compression by removing the cause. (4) The surgical principles can be applied to the lung as to other organs of the living body. (5) The bony chest may be opened for exploration of the lung with as little danger as opening the abdomen, cranium, articulating capsule, kidney, liver, pancreas, spleen, stomach, gut, or hepatic duct. (6) Hermetically closing the chest is irrational, unscientific, and dangerous. (7) Closing the chest wound by any means does not prevent the escape of blood from injured pulmonary vessels into the pleural cavity. (8) All wounds of the chest wall, whether penetrating or non-penetrating, should be treated aseptically, and with reference to drainage. (9) No instrument or needle should be made to enter the lung tissue for exploration, or

the removal of fluid, unless the bony chest has previously been opened. (10) Foreign bodies in the bronchia or parenchyma of the lung may be detected with a fine exploratory needle through an open chest, with the lung contracted. (11) Foreign bodies in the lung and bronchia, when causing serious symptoms, should be removed. (12) Some small foreign bodies become encysted and remain harmless. (13) The position of a foreign body in the lung changes with expansion and contraction of the lung. (14) Hemorrhage, when due to pulmonary tuberculosis, should not be allowed to become fatal without opening the bony chest, and the application of pressure, by forceps, gauze, or otherwise. (15) Bleeding of the lung from any cause will, in many cases, cease when the lung is allowed to contract upon itself, with an open chest. (16) Blood clots within the pleural cavity should be removed at the time they are discovered, whether infected or not. (17) Blood clots in the pleural cavity may become organized with or without adhesions of the parietal and visceral pleura, or they may become infected and cause more serious consequences. (18) Hæmoptysis may be absent in the most severe lacerations of the lung. (19) If bleeding from larger pulmonary vessels results, forceps should be applied; if not, gauze should be securely packed in the cavity. (20) Drainage of pulmonary cysts of any character can be effected with the same success as in any other organ. (21) Incision for drainage should be done with or without the presence of adhesions. If without adhesions, the opening in the chest should be at the lowest point of the pleural cavity for drainage by gravity. (22) Many incisions of the lung may and should be made with and without even local anæsthesia. (23) It is probable that but a few will necessitate the use of general anæsthesia. (24) Abscess of any character and of any location in the lung should be found and opened. (25) Gangrene of the lung demands most radical surgical measures, such as opening the chest, drainage, and the removal of all necrotic tissue. (26) Polypi of bronchia seldom necessitate removal, but they may cause conditions which may require surgical intervention.

Pneumonorrhaphy.—(1) Silk, silkworm gut, and animal tendons are the most desirable materials for lung surgery. (2) Absorbable sutures and ligatures, as a rule, are not to be relied upon as to strength and durability. (3) Silk and silkworm gut may become encysted in the lung and remain harmless. (4) The tug, and a combination of the tug and tobacco-pouch sutures constitute the most desirable ones for use in the lung. (5) Ligatures and sutures may be dislodged by sudden expansion of the lung due to sudden closure of the opening in the chest wall. (6) The blood vessels, bronchia, and lung tissue should be ligated separately, great care being used not to include too much tissue of any kind in one ligature. (7) Needles to be employed in lung tissue should be round, with a rounded point. They should never have a sharp point, or sharp edges. (8) Not all ruptures, punctures, or lacerations of the lung require sutures, or any surgical intervention whatever. (9) Many lacerations of the lung without fracture of the bony chest can and should be treated by suture, compression with gauze or forceps. (10) Puncture of the lung from any cause, such as stab and gunshot, resulting in hemorrhage, should be treated by opening the chest and applying ligature or compression. (11) Rupture of the the lung should be treated as a laceration.

Pneumonectomy.—(1) A portion or all of one lobe, or the entire right or left lung, may be removed without causing death. (2) For complete or partial lacerated portions of the lung, when severe, pneumonectomy is necessary, and should be done. (3) Gangrene of the lung requires, in many cases, the removal of all necrotic tissue. (4) Hernia of the lung, when sudden and of but few hours' duration, should, as a rule, be amputated, and the stump fixed in the chest wall, as there is no sac. (5) Hernia of the lung coming on gradually has a sac, and should be returned to the pleural cavity, if possible, without amputation.

Pneumonopexy.—(1) This is the safest and most rapid way of dealing with the stump of lung tissue in the majority of cases, necessitating excision for any cause. (2) Adhesions of the parietal and visceral pleura have, without exception, taken place, whether there have been lacerated or incised wounds, with or without suture. (3) The degree of adhesion corresponds with the degree of injury. (4) Cysts of the lung of any character can best be drained through viscero-parietal adhesions. In the absence of adhesions, the walls of the cysts may be sutured to the edges of the opening in the chest wall, drainage to be at once accomplished or at some subsequent time.

SECOND DAY—MORNING SESSION.

The Pathology that Remains after the Non-surgical Treatment of Peritonitis.—Dr. H. D. Niles of Salt Lake City, Utah, read a paper on this subject in which he stated that 95 per cent. of all the survivors of the non-surgical treatment of peritonitis were left with infection without the peritoneal cavity, and adhesions within this cavity. Well-known anatomical peculiarities of the gall-bladder, appendix, and Fallopian tubes favored the reception and imprisonment of infection from the alimentary canal and endometrium, and its extension to the peritoneum. It was about one of these organs that the surgeon usually found the pathology, unless it had been mechanically removed. The greatest amount of infection came from a sudden rupture of an appendiceal or tubal abscess, or a perforation of the stomach, intestine, or the gall-bladder. The most virulent infection was either appendiceal or from a pyosalpinx following a puerperal endometritis. The mildest was from a cholangitis or a gonorrhœal salpingitis. The author's experience led him to believe that about 40 per cent. of the possessors of infection and adhesions suffered from recurrent attacks of acute and subacute peritonitis, and less than 1 per cent. from mechanical obstruction of the bowels. It was to the remaining 59 per cent. that he invited particular attention, for, while it was customary to point to these cases as sufficient proof of the efficacy of the drug treatment of peritonitis, he believed that all fair-minded, thoughtful observers were learning to regard the pathology these patients carried within their abdomens as responsible for much distress and many deaths that were formerly attributed to other causes, or for which no well-defined cause could be found.

Surgical Treatment of Tuberculous Peritonitis.—The author of this paper, Dr. D. S. Fairchild of Clinton, Ia., drew the following conclusions: (1) If an intraabdominal focus of tuberculosis is diagnosed or is suspected, an abdominal section should be made with the view of more efficient treatment. (2) If a chronic tuberculosis of the peritoneum, with ascites, is diagnosed, or believed to exist, a laparotomy is indicated as soon as it is found that medical and hygienic treatment has failed. (3) In fibrous tuberculosis of the peritoneum the same course should be pursued, and if cheesy degeneration has not commenced, or progressed too far, a certain percentage of recoveries will follow. (4) In acute tuberculous peritonitis, with ascites, and high temperature, laparotomy is useless. (5) In extensive adhesive tuberculosis of the peritoneum, with matting of the intestines, laparotomy is useless, and the attempt to separate the adhesions is dangerous in its immediate results.

Injury to Nerves Following Fractures.—Dr. A. L. Wright of Carroll, Ia., read a paper on this subject, in which he reported a case of fracture of the humerus through the middle third, with injury to the musculospiral nerve, or, rather, the incorporation of this nerve between the ends of the bone, or to its being caught and pressed upon by the callus thrown out during the reparative process. He stated that the literature was replete with cases reported in which various nerves, especially the ulnar and median nerves, had been severed by a stab

or the falling of glass. The case presented by him had the typical clinical picture of injury to a nerve found at the end of a siege with a fractured bone, and taught a very valuable lesson regarding the prognosis and treatment.

Treatment of Nævi.—Dr. John P. Lord of Omaha, Neb., followed with a paper on this subject. He discussed the varieties of nævus, their etiology and pathology, and reported several interesting cases. He stated that the hot-water treatment of cavernous angiomas, as suggested by Wyeth, was under trial, and would doubtless have a place in the treatment of selected cases. The treatment of port-wine marks by electrolysis was too tedious and painful for large areas. The results were not perfect, in that they were seldom complete, and left some scarring. The *x*-ray promised better, and hot air would seem to have possibilities. Electrolysis occupied first place in hairy nevi, and would probably continue to do so unless the *x*-ray would produce permanent atrophy of the hair follicles. The operation of excision of very large tumors would probably never be supplanted by anything less radical; and hitherto inoperable tumors were rapidly yielding to the control of the operators of the new century.

Hypernephroma.—Dr. M. L. Harris of Chicago presented a paper with this title. He said that it was only during the last few years that our knowledge of tumors of the suprarenal capsule had made any material progress Previous to this time tumors were variously described as adenomata, sarcomata, carcinomata, mixed sarcoma and carcinoma, endotheliomata, etc. The essayist referred to the literature of this subject and to cases previously reported, and after giving the details of a very interesting and instructive case, presented the following conclusions: (1) The hypernephromata are tumors of adrenal tissue, and therefore probably neither sarcomatous nor carcinomatous. (2) Such tumors may or may not form metastases. When they do, they are distinctly malignant. (3) When they are within the kidney capsule, or have perforated it by extension, the kidney should be removed. (4) When they originate in the adrenal tissue proper, they are usually separated from the kidney tissue by a connective tissue capsule, and however much the kidney may be flattened or fixed to the tumor, a line of cleavage may usually be found which will permit of the kidney being separated from the tumor and saved to the patient.

Dr. C. W. Oviatt of Oshkosh, Wis , reported a case of hypernephroma, which came under his observation about four years ago, but at that time a diagnosis was made of sarcoma of the kidney.

Dr. Van Buren Knott described a case of hypernephroma in a woman, thirty-eight years of age. This case came under his observation about eighteen months ago. A diagnosis had been made by mistake of semi-solid tumor of the ovary

Dr. A. C. Bernays of St. Louis, Mo., reported six cases of hypernephroma.

SECOND DAY—AFTERNOON SESSION.

Two Cases of Acute Intestinal Obstruction Following Contusion of the Abdominal Walls.—This paper was read by Dr. J. E. Summers, Jr., of Omaha, Neb. In the first case there was traumatic paresis of the lower part of the small intestine following kicks upon the abdomen. The patient was a man, twenty-six years of age, and of good physical development. The second case was one of retroperitoneal hemorrhage following a contusion of the abdomen, resulting in a hæmatoma, which compressed the descending and transverse portions of the duodenum from behind so as to cause intestinal obstruction. The patient was a rugged young man, twenty years of age, and a farmer by occupation.

A New Method of Shortening the Round Ligaments Intraperitoneally for Retroversion of the Uterus.—Dr. Henry T. Byford of Chicago read a paper on this subject and described this new method, as follows: "It consists in folding the ligaments anteriorly, according to Dudley, but in stitching the loop to the abdominal parietes, about opposite or behind and a trifle above the internal inguinal ring The ligament is grasped with hæmostatic forceps, and pulled out of the abdominal incision until it is drawn as far out of the inguinal ring as possible, without doing violence to the tissues. Then a medium-sized catgut suture is passed through the center of the ligament about a quarter of an inch from the uterine end, and the same suture is passed through the ligament about half an inch from the internal inguinal ring. The suture is then drawn tight and tied like an ordinary ligature, except that it includes only half of the ligament in its grasp. The inner edges of the loop thus formed should now be touched with a chemical irritant, such as Monsell's solution or 1-5,000 mercuric bichloride, in order to destroy the endothelium and secure firm adhesions. The irritant is then wiped off and the edges sewn together by fine catgut, which entirely closes in and covers up the irritated peritoneal surfaces. The end of this fold is then touched with the chemical irritant, and stitched forward beside the bladder, about opposite and a little above the level of the external inguinal ring. This, of course, will be only a peritoneal attachment, and should be rather high, because the peritoneum is held in place here rather loosely. Thus there are practically two round ligaments on either side, one going from the uterus partly through the first catgut ligature to the attachment behind the external inguinal ring, and the other from the uterus to the ligature, and from there to the internal inguinal ring, etc. The uterine half or quarter inch, or inch, according to the place where the ligament is transfixed, is common to both of the newly-formed round ligaments."

In case there was a tendency to uterine prolapse, the author sutured the whole side of the fold of the ligament to the peritoneum beside the bladder, or even sutured the portions of the round ligaments external to the folds to the parietal peritoneum in front. When there was decided prolapse, he also stitched the infundibulo-pelvic ligament forward, the fundus uteri itself, and even took folds in the sacrouterine ligaments. When there was cystocele, he separated the remains of the urachus with a narrow strip of peritoneum, and after loosely twisting the flap thus obtained, and drawing up the bladder, attached the flap into the abdominal wound.

Dermoid Cysts of the Intestinal Tract.—Dr. William Jepson of Sioux City, Iowa, presented a paper on this subject and reported a case. The cyst occupied the anterior internal wall of the colon about three-quarters of an inch above the ileocæcal valve. It was covered by peritoneum through which the cyst wall was plainly seen. The cyst was removed by making an elliptical incision through the serosa and dissecting out the growth. Recovery was uneventful. In explanation of the development of congenital cysts in the intestinal tract, the author stated that the following theories had been advanced: (1) Imperfect obliteration of the omphalomesenterie duct. (2) Torsion of a portion of the intestinal wall by the products of a previous peritonitis, etc. (3) By sequestration or implantation of epiblastic or hypoblastic structure leading to the later development of an ento- or ecto-dermoid. The point of interest which these cysts had for surgeons were (*a*) that in a large per cent. of the cases the cysts, although innocent in themselves, ultimately led to a fatal issue, either through obstruction of the intestinal lumen, or because of their contents becoming infected from the intestinal canal, terminating in peritonitis. (*b*) If their removal was undertaken before such complications had resulted, a favorable termination could be looked for.

Appendicitis—Operation and Indication.—Dr. A. C. Bernays of St. Louis, Mo., contributed a paper with this title, in which he laid stress on the fact that we knew nothing definite relative to the pathological process which war-

ranted delay in operating. We did not know enough before opening the abdomen to warrant us in following an expectant plan. He believed many lives were lost because the physician was lulled into hopeful security by an amelioration of symptoms. This amelioration could not be depended upon to last, as it might change, without a moment's notice, into a sad picture of collapse and sepsis, and the favorable time for operation was missed.

In so-called intermediate cases a waiting policy was justified because the system was immunizing and fortifying itself against the toxins. An operation after the body had been immunized, which meant that the pus had been made less virulent, was less dangerous. Dr. Bernays thought that an operation was likely to be less dangerous on the seventh or eighth day than on the third or fourth, but made a strenuous plea for operation on the first or second day of the attack, and claimed that 98 per cent. of all cases operated on at that early period would be saved. Operations done on the first or second day of the attack were as safe as internal operations. The most brilliant and satisfactory results followed prompt operations in cases of severe appendiceal peritonitis.

Hyperplasia of the Uterus.—Dr. C. G. Geiger of St. Joseph, Mo., read a paper on this subject. He stated that the frequent occurrence of enlargement of the uterus had been a great stimulus to the study of its underlying pathological conditions. The most frequent causes of hyperæmia were puerperal subinvolution of the uterus, which might be caused by too early getting up after childbirth, small or large lacerations of the cervix, and uterine trouble. Anything which interfered with normal involution predisposed to this condition. He mentioned three distinct stages of hyperplasia—hyperæmia, hypertrophy, and sclerosis.

It was impossible to determine at the bedside exactly when the state of subinvolution began to emerge into that of hyperplasia, as it was a slow and insidious development. The two affections in clinical appearance resembled each other, and apart from the history differentiation was difficult. Chronic hyperæmia and hyperplasia might involve any portion of the uterus, neck or body, or certain portions thereof. For manifest reasons, the neck of the uterus was the favorite focus of disease.

The treatment of the various conditions of enlargement was so dependent on their causation that each individual case demanded a separate investigation. He said the ideal way of approaching this subject was in the direction of prevention, which, in a great many cases, the attending physician was able to do. But gynecologists must meet the disease already developed and devise methods which, if not curative, were palliative. Iodine and caustics in the hands of the essayist had not been of much service. In neurotic patients nothing was better than a change of climate and scenery. In some cases a change in the surroundings accomplished much good. To sum up the treatment briefly, the patient should be given rest, the cause removed, the diseased organ depleted, and the patient's general health improved.

Some Questions in Abdominal Surgery.—Dr. J. N. Warren of Sioux City, Iowa, read a paper on this subject.

Officers for the Ensuing Year.—The following officers were elected: *President*, Dr. Alexander Hugh Ferguson, Chicago, Ill.; *First Vice-President*, Dr. C. H. Wallace, St. Joseph, Mo.; *Second Vice-President*, Dr. C. W. Oviatt, Oshkosh, Wis.; *Secretary* and *Treasurer*, Dr. George H. Simmons, Chicago, Ill.; *Members of the Executive Council:* Dr. James E. Moore, Minneapolis, Minn., *Chairman;* Dr. A. F. Jonas, Omaha, Neb.; Dr. O. B. Campbell, St. Joseph, Mo.; Dr. C. H. Mayo, Rochester, Minn.; and Dr. J. R. Hollowbush, Rock Island, Ill.

Denver, Colorado, was selected as the place for holding the next annual meeting; time, December 28 and 29, 1903.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 22, 1902.

Charles N. Dowd, M.D., President.

Some Common Skiagraphic Errors; Cause, Dangers, and Prevention of the Same.—Dr. Lewis G. Cole read this paper. He called attention in cases of Colles' fracture, for example, to the necessity of carefully noting the relations of the bony parts. To do this properly the surgeon should draw a line parallel with the outer edge of the ulna, and another at a right angle to this, at the articular surface of the head of the ulna. He should then observe what relation the base of the radius bore to the head of the ulna. Normally, the styloid process of the radius extended from a half to three-quarters of an inch below this line. The causes of error in skiagraphy were: (1) Varying the distance of the tube from the plate; (2) varying its direction from the plate; (3) varying the distance of the tube from the body; (4) varying the direction of the tube in relation to the body; (5) varying the distance of the body from the plate; (6) varying the relation of one bone to the other; (7) varying the relation of the part skiagraphed to the body as a whole, and (8) varying the angle at which the light strikes the plate by tilting the plate. By means of a series of diagrams the author illustrated the distortions produced in skiagraphs by these variations in the adjustment of the apparatus, and of the part to be skiagraphed. Three of the diagrams showed that, by a change in the position of the *x*-ray tube, the resulting skiagraph could be made to indicate either an overlapping or a separation of the fragments. The author said it was not safe to compare a skiagraph with an anatomical plate showing the normal appearance of the part in question; nor was it safe to compare a skiagraph of a limb of one person with a skiagraph of the same limb of another person. The only safe method was to compare the skiagraph of one limb with a skiagraph of the corresponding limb of the same person. Dr. Cole then showed a skiagraph of his own arm, taken in such a way as to make it appear that his arm was the seat of a Colles' fracture, though such was not the case.

The Detection of Renal and Vesical Calculi by Means of the X-Ray.—Dr. Henry P. Moseley was the author of this paper. He said that on July 11, 1896, the first case of diagnosis of a renal calculus by the Röntgen ray had been published. In that case the diagnosis was subsequently confirmed by operation. Before attempting to examine a person for renal calculus by the *x*-ray the bowels should be most thoroughly emptied by a cathartic, and by enemata, and the patient should be forbidden to take more than very light food for the twenty-four hours preceding the examination. This would help to exclude shadows formed by fruit stones, and would reduce to a minimum shadows of air-bubbles in the bowel. A plate measuring 11 by 14 inches would usually be large enough. The *x*-ray tube should be placed directly over the umbilicus at a distance of 18 inches from the plate, and two radiographs should be taken at an interval of several days. Renal calculi composed of oxalates or of phosphates gave the best shadows. In attempting to diagnosticate vesical calculi by the *x*-ray, the patient should be placed upon the belly and the bladder should be empty. The fluoroscope was not suitable for this kind of work, for the shadows are very delicate, and it should be remembered that in order to do good work with the fluoroscope the examiner should remain in a dark room for ten minutes before making the examination. A number of interesting skiagraphs were exhibited by Dr. Moseley.

The Limitations of the X-Ray in the Treatment of Cancer.—Dr. William B. Coley read this paper. He said that during the past year he had seen seventy-five malignant tumors treated by the *x*-ray. Of this number twenty-seven were sarcomata, and twenty were cases of

cancer of the breast. Five round-cell sarcomata were entirely cured. In sixteen of the cancers of the breast the disease was recurrent and inoperable. Frequently recurrent nodules disappeared entirely in a few weeks of treatment by the *x*-ray, but they very soon reappeared. This showed that while the *x*-ray exerted a marked influence on malignant disease, there was a tendency to speedy recurrence. Thus far there had not been a single case of cancer that had remained well sufficiently long to consider it a cure. He believed the interest of both science and of our patients would be best served by limiting the *x*-ray treatment to inoperable cases. This treatment was only in the experimental stage. He was free to admit that two-thirds of the cases of cancer, surgically treated, recur after a longer or shorter time, and these cases should afford, for the present, sufficient opportunity for testing the value of the *x*-ray treatment. The laity had already jumped to the conclusion that in the *x*-ray was to be found a successful substitute for surgical operation. He had personally treated twenty cases of recurrent cancer of the breast with the *x*-ray, yet, in not a single instance had any large recurrent tumor completely disappeared, although in some instances the treatment had been kept up for eight months. If the so-called cures after *x*-ray treatment were subjected to the same standards as those treated by surgical operation, there would not be many cures; on the other hand, while some had reported as high as 50 per cent. of "cures" from the *x*-ray, it was probable that if the cases surgically treated were judged by the same standard, they would show at least 75 per cent. of "cures."

Demonstration of Tubercle and Other Bone Lesions from X-Ray Negatives.—Dr. Louis A. Weigel of Rochester gave this demonstration, and made some remarks on the use of the *x*-ray in the diagnosis of bone tuberculosis. He said that an *x*-ray plate, to be of any value for any purpose whatever, whether for fractures, renal calculi, or bone disease, should be an exceptionally good one, because any other kind of plate was worse than useless, being absolutely misleading. It was not particularly difficult to make a good *x*-ray plate. Those which he would show had not been retouched or intensified. A large series of excellent skiagraphs were then exhibited and commented upon.

Permeability and Composition of Calculi.—Dr. A. B. Johnson spoke in commendation of the efforts made by Dr. Cole to point out clearly the causes of errors in radiography. This was a subject of the utmost importance in medicolegal work. He had himself taken upward of 200 radiographs of persons supposed to have renal calculi, and of this number stones had been found in about thirty, and in almost all of those operated upon the diagnosis had been found correct. He did not think it possible in the case of a very stout person to make a radiograph which would clearly show a renal calculus. Many of his failures had been due to faulty technique in the preparation of the negatives, while others had been due to the use of improper *x*-ray tubes. It was necessary to use excellent *x*-ray tubes, and tubes which had been but little used. All of the stones detected by this means contained some other ingredient besides uric acid. This had led him to make a series of experiments, to determine the permeability of kidney stones of varying composition. He had collected a large number of such stones, and, on having them analyzed, had found that very few of them were wholly composed of uric acid. He found the latter to be so permeable that he would not be willing to express an opinion regarding the shadows cast by them under the *x*-ray. On the other hand, if there were only 10 per cent. of calcium phosphate, the shadow would be quite distinct, almost as much so as if the stone were wholly made up of calcium phosphate. In one case he had been able to detect, in a man weighing 170 pounds, the presence of a stone in the ureter weighing only 1¼ grains. It was composed of oxalate of lime.

X-Ray Fails to Prevent Dissemination of Cancer.—His own experience with the *x*-ray treatment of malignant disease had been very similar to that of Dr. Coley. He had apparently cured a few cases of sarcoma, but none of carcinoma, and all of his cases had been inoperable ones, because he did not believe in subjecting other cases of malignant disease to this comparatively new and untried treatment. Some of his cases had developed carcinoma of the liver under treatment, and also nodules in the vicinity of the original growth, and that, too, when no screen had been used. One patient came to him with a few minute nodules of carcinoma of the skin, which had developed after an amputation of the breast for carcinoma. No screen was used, yet the patient developed carcinoma of the liver and of the parotid gland, and eventually died from the disease. Hence, so far as the dissemination of the disease was concerned, his own experience did not indicate that the *x*-rays had any influence in preventing this, although the local lesions evidently improved. These cases were favorable ones, because they were all private patients, who had plenty of money and time, and were willing to submit to any amount of treatment. He did not think any one to-day should recommend *x*-ray treatment of malignant disease in preference to operation, except when the disease was inoperable. He could hardly find words to thank Dr. Weigel for his wonderful demonstration of skiagraphs of bone disease. He did not think there was another equally good collection of skiagraphs in this country. He agreed fully with Dr. Weigel that it was folly to attempt to make a diagnosis of bone disease, except from *x*-ray negatives of the first quality.

Dr. H. Lilienthal observed that *x*-ray work was essentially a specialty, and hence the surgeon should not do such an operation as an amputation without first satisfying himself that the *x*-ray negative furnished had been produced by an expert in that field, and that his interpretation of the plate corresponded with the clinical record of the case. With regard to cancer, he would say that an operable case was one in which a cure could be effected with fair certainty by operation, or in which the disease could be so modified as to prolong the patient's life considerably, or in which the patient could be relieved of painful or loathsome conditions. In such cases he believed the *x*-ray should come after, and not before, the operation. In a clearly inoperable case the *x*-ray should be used. For example, in an infiltrating carcinoma of the jaw, involving the soft parts and the glands of the neck, there could be no doubt that the patient was doomed, and that operation would not only produce horrible disfigurement, but might shorten life. As it was not justifiable to do a radical operation in such a case, the *x*-ray should be called to the aid of the surgeon. He also wished to thank Dr. Weigel for his excellent demonstration, and to ask him if it were possible to get better definition in the examination of the *x*-ray negative for suspected gallstones by using with Dr. Weigel's box blue, red, or green light instead of a white electric light.

Dr. Weigel said that from what he had seen of the work in the field of gallstone skiagraphy, he felt that the skiagraphs could have been better made by a different technique. A tube which would perhaps give the best definition in bone would not always give the best definition in the soft parts; yet he did not believe it was wise to use a "low" tube. What was wanted was an *x*-ray tube which would give penetration. The object should be to obtain a first-class negative, and if this were attained, it did not make very much difference whether it was illuminated by a white, a red, a green, or a blue light. He was inclined to think, however, that the white light, with his box, would give the best definition, but it should be remembered that often the light shadows would not be visible, unless the observer took a position which would allow of looking obliquely through the photographic film. The ordinary method of examining an *x*-ray negative, by

holding it up to a window, was crude and unsatisfactory, and one would be surprised to find how much could be seen by making use of his box.

X-Ray Fails in Deep Cancer.—Dr. Franz Torek said that he agreed with the previous speakers that *x*-ray treatment should not be used in operable malignant growths. He had begun this treatment of malignant disease with some enthusiasm, owing to a number of very beautiful results in superficial epithelioma of the skin. He had, however, come to the conclusion that the more deeply-seated tumors could not be cured, with any degree of certainty, by the *x*-ray, and that this treatment should be limited to inoperable tumors, with perhaps, the one exception of the superficial epitheliomata of the skin. In the last-mentioned field there was still justification for trying the *x*-ray treatment, even in cases which might be successfully attacked by the knife. Of course, the *x*-ray treatment should be employed in cases of malignant disease after the use of the knife. His experience, so far, comprised the *x*-ray treatment of thirty-five cases of malignant disease.

Dr. Eden V. Delphey spoke of a method of examining cases of supposed fracture with the fluoroscope, and having obtained the desired position, substituting the photographic plate and making an *x*-ray negative. It was essential to select a tube giving a proper degree of penetration. The size of the target was also of importance. The speaker pleaded for greater exactitude in *x*-ray work, particularly in the matter of "dosage."

Dr. Delphey then presented a young woman who had been to a great many physicians without relief. After a careful and systematic examination of all the organs with negative result, she was subjected to an *x*-ray examination, and this revealed in the neighborhood of the fourth dorsal vertebra an aneurysm of the descending arch of the aorta. There was no tracheal tug or any of the usual symptoms of such aneurysm. An *x*-ray photograph would not show the condition, but it was plainly revealed by fluoroscopic examination. The case was presented to show the value of this special mode of examination under certain conditions, and the need for varying the technique to adapt it to the individual case.

Report of Committee on Coroners' Office.—This committee reported in favor of the abolition of this office and the separation of the medical and judicial duties of that office, after the manner now in vogue in Massachusetts. After some discussion, on motion of Dr. Theodore K. Tuthill, it was voted to call a special meeting in the near future for the consideration of this subject.

Overcrowding of Street Cars.—A committee was appointed to draft suitable resolutions on this subject, expressing a willingness to co-operate with the Merchants' Association, said resolutions to be submitted to the society for its approval.

The Treatment of Arteriosclerosis by Subcutaneous Injections of Inorganic Serum.—Dr. Trunecek has prepared a solution to which he gives the name of "inorganic serum," which is a mixture of the sulphate, chloride, phosphate, and carbonate of sodium, sulphate of potassium, and distilled water, which he injects subcutaneously in cases of arteriosclerosis. The degree of the urinary acidity, as well as the desquamation of the integument, are the chief signs on which we must rely to commence, suspend, or recommence the treatment. The alkaline salts render soluble the phosphate of lime which has been deposited upon the arterial walls, increase the activity of organic combustion, restore the intercellular exchange to approximately their normal standard, and consequently regulate the functions of the various systems, especially those of the heart and the blood vessels.—*Medical Press and Circular*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 3, 1903.

	Cases.	Deaths.
Measles	118	8
Diphtheria and croup	322	45
Scarlet fever	150	10
Smallpox	4	..
Varicella	80	1
Tuberculosis	190	142
Typhoid fever	68	17
Cerebrospinal meningitis	3	..

Means of Obtaining a Bacteriological Diagnosis of Plague.—Mr. Frank Tidswell of Sydney, writing on this subject says, "We never attempted to incise a bubo, save in the hospital, on account of suppuration; the fluid for diagnostic examination being always obtained by puncture, and aspiration with the needles and syringe, after preliminary cleansing of the skin. Any fluid obtained was conveyed to the laboratory in the barrel of the syringe, and there taken from it to inoculate culture tubes and a guinea-pig, and to make cover-glass preparations. Sputum was taken in the sterilized wide-mouthed bottle, and at the laboratory treated in the same way as bubo fluid. With blood the culture tubes were inoculated, and cover-glass smears prepared at the bedside of the patient. Puncture of a bubo did not always yield fluid for examination. In the early stages success depended on puncture of the swollen gland itself, which had to be defined and studied between the thumb and finger of the left hand, whilst performing the small operation. In the later stages this was less important, as the exudation round the gland contained abundance of plague bacilli. The amount of fluid obtained was rarely more than a few drops, and in some instances, when none appeared in the barrel of the syringe, one could still obtain enough from the channel of the needle. It was also possible, in some cases, to express a drop or two of fluid out through the needle track, by gently squeezing the bubo; and with the small quantity so obtained to make cultures and smear preparations, as in the case of blood. The fluid obtained at these examinations was seldom purulent, but usually a greyish-colored mixture of lymph and blood, containing innumerable plague bacilli. Our experience was similar to that of other observers, in that bacilli were relatively scanty in pus from suppurating buboes. Specimens of blood rarely showed plague bacilli, save when taken from patients who died within twenty-four or forty-eight hours afterward, and even in these the microorganisms were usually few, and discovered only after long search. The cultures from blood were more useful, so far as recovery of bacilli was concerned, but the patient was generally dead by the time one could examine and pronounce upon the growth. It afforded confirmatory, rather than diagnostic assistance, and this applies, also, to guinea-pigs inoculated from the small clots often found on the culture tubes inoculated with the blood. I have nothing special to remark with regard to sputum, as very few samples came under my notice."

The Importance of Hyaline Casts in the Diagnosis and Prognosis of Renal Diseases.—A. R. Defendorf states that purely hyaline casts have been found in large percentages in individuals who are apparently healthy, and without other evidence of kidney disorder. These percentages increase with the advance of age. This in the absence of post-mortem observations, has led to a more or less general belief that hyaline casts in the urine of individuals past fifty are without significance. A series of forty-eight autopsies, in which urine examinations had been made some time previous to death, shows that casts were present

in forty-one cases, and chronic nephritis in forty-seven, permitting the inference that hyaline casts in these cases were distinctly an indication of an organic disease of the kidneys. The five disease conditions in which hyaline casts exist alone or with finely granular casts are: The atrophic stage of chronic parenchymatous nephritis chronic interstitial nephritis, chronic diffuse nephritis, senile interstitial nephritis and chronic passive congestion of the kidneys. The prognosis of these conditions, with the exception of passive congestion, depends as much upon the general clinical condition of the patient, especially in reference to cardiac and vascular disease, as upon the character of the kidney lesion.—*Yale Medical Journal.*

Polyhydramnios; Its Differential Diagnosis and Treatment, with the Report of Cases.—Edward P. Davis says that by this term is meant more than two pints of amniotic liquid at full term. As much as seven gallons has been seen in the human species. Many conditions accompany polyhydramnios. The placenta is often large, dropsical and infiltrated, Jungbluth's vessels often enlarged, the amnion and chorion may be thickened with extensive fissures in the epithelial layer of the amnion, and fatty degeneration of the cells. The diagnosis is made by first diagnosticating pregnancy, then by observing that in polyhydramnios we can usually obtain evidence of faint uterine contraction and can often insert the finger through the cervix and detect a presenting part. Estopic gestation must be kept in mind, as polyhydramnios may complicate it. In ovarian cyst the illness is longer, the swelling at first unilateral. The intermittent hardening of the tumor is absent, and the uterus can be found but little enlarged. In ascites the dulness changes when the position of the patient is altered. Treatment by drugs is without value. When distension increases rapidly and the patient's health is impaired, under thorough antiseptic precautions the cervix should be dilated sufficiently to admit the finger. Fluid should be allowed to escape very gradually until the presenting part descends firmly against the cervix. Firm pressure must be made over the abdomen, and the patient must be watched, as labor is often precipitate, and the fœtus may assume unfavorable positions.—*Annals of Gynecology and Pediatry.*

Abortive Treatment of Felon.—Joseph Rilus Eastman states that in nearly all cases a felon may be aborted by the application of pure alcohol under exclusion of the air. As soon as the diagnosis is made, the involved phalanx should be covered with a thin layer of sterile absorbent cotton saturated with alcohol. Over this a thin rubber finger stall should be applied. The finger stall should be rolled upon itself from the open end toward the apex and applied over the cotton by unrolling. In the simple form of felon caused by the introduction of staphylococci into the rete malpighii, restitution of the tissues occurs very promptly under the alcohol treatment. In deep cellulitis with inflammatory infiltration and abscess, pain and tenderness usually subside within seventy-two hours. It may be said in criticism of this treatment that a means for escape of pus should be provided early by a free incision. In severe septic cases the tissues should, of course, be promptly and deeply incised, in order that spreading may be forestalled or checked, but in simple cases incision may not only be unnecessary but reprehensible.—*The Medical and Surgical Monitor.*

Treatment of Cerebral Rheumatism by Cold Baths.—M. Shellenburg reports the case of a man suffering from this affection, who had a temperature of 104° with rapid pulse and respiration. Delirium came on very suddenly, was transitory in its nature, disappearing when the temperature fell 2 degrees. The application of the ice bag to the head and sponging of the body not proving of permanent benefit, baths were ordered, with the result that the temperature dropped and the delirium disappeared. The patient eventually recovered. There has been some objection to the use of the bath on the ground that the other conditions would not permit of such a therapeutic measure, but we must remember that in hyperpyrexia and cerebral complications there is a high degree of mortality, and it is possible that by resorting to the bath the fatal issue may be avoided.—*Albany Medical Annals.*

The Diet of the Asthmatic.—George N. Jack thus concludes his study of the subject. If on a differential count the blood shows a high percentage of small lymphocytes, milk should be diminished or withheld. An abnormal increase in the polymorphonuclear neutrophilic cells indicates an intestinal toxæmia and putrefaction which suggests the withholding of meat food. A pronounced iodophilia indicates an amyloid or starchy degeneration of blood, and suggests the withholding of foods rich in starch. A thin, watery blood with a deficient plasma and a red corpuscle, poor in hæmoglobin and deficient in biomagnetism, as shown by the lack of rouleaux formation and the scattering of the red blood-corpuscles about the field, indicates the giving of fresh bloody meat, raw eggs, and green vegetables, rich in chlorophyll and protoplasm —*Buffalo Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending January 3, 1903:

SOME QUESTIONS IN HEREDITY.*

BY A. ALEXANDER SMITH, M.D.,
NEW YORK.

AT the very outset I wish to emphasize the fact that in this paper I have limited myself to certain phases of heredity. The subject is such an extensive one, and can be approached from so many different standpoints, that it would be difficult for one to encompass it entirely. I have, therefore, limited myself largely to that phase of heredity which has a bearing upon our every-day clinical work. I have made no attempt to discuss the subject from the standpoint of the biologists, nor have I touched upon the question of longevity or that of susceptibility to certain kinds of foods or drugs.

Every practitioner of medicine is brought face to face almost daily with questions of heredity, and such questions present always very complicated problems. I think it may be admitted at once that heredity often has a very marked bearing upon disease, both acute and chronic, not only in the susceptibility to the development of such disease, but it has also a bearing upon the questions of tolerance and prognosis.

Since the publication of Koch's paper upon the isolation of the tubercle bacillus, and one might say since the publications of Pasteur at a little earlier period, our ideas upon the influence of heredity have been very decidedly modified. We must recognize at once that many diseases, formerly supposed to be directly transmissible, are now believed to be the results of direct infection. It is possible, and, indeed, not at all unlikely, that still more diseases will be found to be dependent upon infection directly, although hereditary proclivities may have more or less influence.

One thinks at once in connection with heredity of the very marked modification of the views on tuberculosis. Pathologists assert, and seemingly with absolute justification for their assertion, that tuberculosis is not directly an inherited disease, but that it is always the result of infection. We all recognize that the most we can say, certainly about *pulmonary* tuberculosis, so far as heredity is concerned, is that the lessened resistance to the attacks of the tubercle bacillus may be inherited. Vulnerability, as it is called, exists perhaps in the tissues. It is not so clear, however, that tuberculosis affecting some other organs of the body is necessarily a direct infection. Take, for example, tuberculosis of the glands, of the skin, of the bones, of the joints, even of other tissues, and it would seem that the last word on the subject has not yet been spoken. Admittedly, the infectious origin in conditions other than pulmonary tuberculosis is not always as easily explained as in the pulmonary variety. The cells of the lungs are less resistant, and the soil seems to be a specially fruitful one for the growth of the tubercle bacillus. But even in pulmonary tuberculosis puzzling questions oftentimes arise.

*Read at a meeting of the New York Practitioners' Society, December 5, 1902.

Congenital tuberculosis is exceedingly rare; a child may be born with the distinct evidence of tuberculosis, but usually one can trace in such cases an infection from the mother while the child was *in utero*, or possibly, in very rare instances, an infection from the genital organs of the father during the life *in utero*. A puzzling question arises in connection with the development of one form or another of tuberculosis; for example. of the gland, joint or bone, in which the parents have shown no evidence of the disease, and yet a grandparent has had tuberculosis in some form.

Another obscure point in connection with tuberculosis is the spontaneous recovery which takes place in a pretty considerable number of cases, in whatever situation the lesion may be, although more readily in some situations than in others. Is such spontaneous recovery due to an inherited tolerance, or is it always due to special circumstances in each individual case, independently of any inherited tolerance? It is often observed in families that certain diseases develop at corresponding periods in the life of parent and offspring. This not infrequently extends through several generations. Tuberculosis is a notable example of this.

The wide-spread prevalence of tuberculosis adds to the difficulty in arriving at definite conclusions, in regard to the part which heredity plays. It is rarely that one can give a history of freedom from the disease in one or other ancestor, either near-by or remote.

Perhaps the next disease one would think of in connection with heredity is gout. This affection has been recognized for many years as one exhibiting hereditary tendencies. It is generally believed that the gouty habit may be hereditary, and that this habit has been brought about by errors in diet, both in eating and in drinking, through many generations. In a large proportion of the instances in which gout can be looked upon as hereditary, the immediate ancestor does not seem to have been alone responsible. Perhaps of all diseases with which we have to deal, the "gouty habit" is the most conspicuous, as having been brought about by a number of generations of such errors. The question is very much complicated by the fact that oftentimes those who inherit the tendency to gout add to it by their habits of life. How often it happens that individuals commit what we consider to be grave errors in diet likely to lead to gout, and yet gout does not develop; on the other hand, the slightest indiscretion in some individuals develops an attack. I do not refer only to gout affecting the joints, but to gout in all of its many and various manifestations. It is recognized that oftentimes gout appears in individuals who have inherited the gouty habit, although their own habits of life are most correct. On the other hand, we do see instances in which the immediate ancestor may transmit the gouty tendency, for not infrequently it happens that the younger members in a family will develop the disease and the older ones escape, because the habits of the immediate ancestor at the time of the birth of these younger ones were such as to lead to the

development of the disease. One must not forget, in connection with gout, as with most other diseases, that environment, and the habits of life, other than those of mere eating and drinking, as well as climatic conditions, must all be taken into consideration.

Is rheumatism an inherited disease? Certainly the clinician would answer the question that in a pretty considerable proportion of cases the tendency may be transmitted. It may not necessarily crop out in the form in which it has shown itself in an ancestor, but, in one form or another, rheumatism, or its tendency, must be admitted to be often an inherited condition. I admit that the term rheumatism, as used by the laity, is exceedingly indefinite—a mere muscular pain, a lumbago, a pain in the shoulder; in fact, a pain anywhere is regarded by the laity as rheumatism; but if we question closely we shall find that not infrequently one parent, and perhaps both parents, have been the victims of rheumatism. The recent observations on the infectious origin of acute articular rheumatism, if proven to be correct, would suggest only a transmitted vulnerability, and place it in the same class with many other diseases of transmitted tendencies.

The apprehension that many feel who have lost an ancestor, particularly an immediate one, from cancer, that they will develop the disease, would seem to have some foundation in fact. In many cases of carcinoma an immediate or more remote ancestor has been a victim of the same disease. Those who deny the heredity of cancer would have difficulty in explaining the occurrence of cases in succeeding generations.

The question of heredity in carcinoma has an added interest, from the statistics collected by Dr. Billings. He showed that the longevity in the State of Maine, in proportion to the population, is greater than in any other State in the Union. He likewise showed that carcinoma is more prevalent in that State, relatively to the population, than in any other State, and that very many of these cases of carcinoma occurred after seventy years of age. In these cases it would be difficult to show the influence of heredity. It is interesting to note that carcinoma is supposed to be favored by civilization, comfort, and intellectual progress, and this has been offered as an explanation of why carcinoma is on the increase.

Bronchial asthma is another disease in which one so frequently obtains a history of a parent or grandparent having been similarly affected. It is another example of the development of the same disease in both parent and offspring, at about the same period of life. I am familiar with instances in which bronchial asthma has affected one or another member of the family through four generations.

We are often asked the question by patients, "Is cardiac disease inherited?" It is not always easy to give a satisfactory answer to this question, because of the fact that so often the query is made by one who is a victim of cardiac disease, and who knows that one or more of his immediate or remote ancestors suffered from the same disease. It certainly must be recognized that in some families there is a distinct tendency to the development of cardiac disease, either of the endocardial or degenerative form—myocarditis and fatty degeneration. So far as its direct transmissibility is concerned, all one can say is that the underlying conditions which lead to the development of cardiac disease may be transmitted.

We may, perhaps, say the same thing with regard to renal disease. We recognize the fact that there is a tendency in successive generations to the development of renal disease, and yet we cannot say that renal disease is a transmissible affection. We can only fall back upon an inherited tendency. In many families the general pathological character of disease which may affect various members seems to be an heirloom, and cardiac and renal diseases are no exceptions.

Arteriosclerosis is another condition which, in recent years, has been looked upon, in a certain proportion of cases, as showing a distinct hereditary tendency. In the vast majority of instances the conditions which stand in an etiological relation are acquired. When arteriosclerosis develops under forty-five years of age, in a large proportion of cases an hereditary tendency can be traced. Indeed, it is not unusual to be able to trace this tendency through several generations.

In this connection we might refer to a condition of the blood vessels which is looked upon, in many instances, at least, as hereditary. I refer to hæmophilia. In almost all cases of "bleeders" it is probable that, besides a favorable condition of the blood, there is a peculiar condition of the walls of the veins. In many such instances, it is possible often to trace the history of such an occurrence in one or more ancestors. Almost all "bleeders" are males, although the mother may have transmitted the tendency, she having received it through a male ancestor. Losser gives the history of the Mendel family: In the first generation of four males, three were "bleeders." In the second generation of thirteen children of two mothers, six males were "bleeders"; seven females were exempt. In the third generation there was but one "bleeder," and he the son of a mother who was a "non-bleeder." This tendency, like that in many other diseases, may be partially or completely eradicated by marriage with those who are exempt. Breeders of animals and growers of plants have often demonstrated by the study of unfavorable tendencies, and by proper breeding, the possibility of eradicating, or at least partially eradicating, such unfavorable tendencies.

A very interesting, but a very intricate subject, is the relation of heredity to disturbances and diseases of the nervous system. I think all will recognize the neuropathic constitution as hereditarily transmissible. Hysteria, tic douleureux, hemicrania, and other forms of neuralgia, are recognized as existing in successive generations, and even some of the grave forms of nerve disease—for example, epilepsy, idiocy, and various mental aberrations are considered to be influenced by heredity. These diseases may not be transmitted in the form in which they occur in the parent, but that heredity has a direct bearing is recognized by all observers. How often do we hear a patient suffering from hemicrania, for example, make the statement, "It is constitutional; my mother, or father or a grandparent had it; it is in the family." The neuropathic tendency may not always show itself in the offspring, as it is in the parent, and may manifest itself differently in different members of the family. Thus, it may take the form of a hemicrania in one member, of hysteria in another, of epilepsy in a third, and so on. The precise expression of the neuropathic constitution may vary greatly from mere eccentricity to insanity. Mental derangement, more than any other disease, is an inherited peculiarity, often occurring in a far-back generation, lying dormant, perhaps, through several generations, and then manifesting itself under unusual external agencies, such agencies being merely the means of bringing the tendencies to life

Is the alcoholic habit directly inherited? Is the craving itself transmitted, or are we to explain the cases of supposed inherited craving on the ground of

deficient mental control, or by the fact that in such cases alcohol is an undue stimulant? The periodical drinker is often believed to have inherited his unfortunate habit—shall we call it—and certainly many individuals who are addicted to the use of alcohol make the excuse that they have inherited, at least the desire for the stimulation from it. The probabilities are that it is a deficient mental control, but this itself may be inherited, and may manifest itself in the desire for the effects of other stimulants than alcohol.

Digestive disturbances are often regarded as inheritances. In our clinical experience we not infrequently are told by a patient that he has "inherited a weak stomach" or "sensitive bowels." There is, apparently, an inherited tendency to digestive disturbances in some individuals, both gastric and intestinal; at all events, there are frequently the same manifestations of digestive derangement in the offspring as have occurred in the parent.

The question of tolerance, when once disease has developed, whether acute or chronic, seems to me to be more or less influenced by heredity. How often it happens, in our observation of an individual who is ill with an acute disease, that if we are to judge by our ordinary standards, the disease will result fatally, and yet how very gravely ill some patients will become and still recover. I cannot look upon it as any other than an influence of the hereditary power of tolerance of acute disease which exists in some persons—indeed, in many persons. Take two of the ordinary diseases as types: pneumonia as a type of the short-duration disease, and typhoid fever as a type of the long-duration disease. How desperately ill a person may become with either one of these diseases and yet recover, while in others, with seemingly as good powers of resistance, the disease terminates fatally. I admit that there are many points to be taken into consideration in connection with such cases, such as the modifications of the progress of the disease by disease in other organs than those affected. We call this inherited tolerance vitality, or we say the patients who recover have good constitutions, and yet I fancy we often mean by these terms an inherited tolerance to acute disease. Again, it not infrequently happens that patients will tolerate for a long time the advancing ravages of chronic disease, although by all the laws of prognosis they should quickly succumb. The surgeons often observe an extreme tolerance in patients with very serious injuries, and not only so, but witness a marked tolerance of certain serious conditions which eventually prove fatal. Take, for example, inoperable carcinoma, or a case in which operation has been refused; how much more prolonged is the tolerance of it in some patients than in others, and that, too, without considering the involvement of surrounding vital organs. Even when moribund, the process of dying occupies a much greater time in some persons than in others. Again, we call this vitality, but I am disposed to look upon it as an indication of inherited tolerance. The prognosis as to time should take into consideration this question of inherited tolerance. Again, in valvular disease of the heart, and in degenerative cardiac disease, without valvular involvement, it is often the experience of everyone of us that it is impossible to make a satisfactory prognosis as to the length of time the patient will live. If we attempt to make a standard, we find in the end that we are obliged to take into consideration the individual himself. Even when grave involvement of other organs, secondarily to heart disease, has occurred, how often it happens that some patients will tolerate these conditions for a much longer period than others. Is it not because of an inherited tolerance to serious organic disease?

Racial peculiarities as to heredity have long been recognized. I will mention only one or two instances, and these in connection with susceptibility. The colored race, in most instances, seems to have very little susceptibility to the microorganism of yellow fever, but a very high degree of susceptibility to that of tuberculosis and pneumonia, especially if removed from the natural tropical climate to a temperate zone. The Jewish race seems to possess a very high degree of resistance against the tubercle bacillus, but is very susceptible to the causes of neuroses, diabetes, and affections of the skin. The tolerance and want of tolerance seem to be inherited qualities.

8 West Forty-seventh Street.

METHODS OF QUARANTINE AGAINST YELLOW FEVER ADOPTED IN HAVANA, CUBA, DURING THE YEAR 1901.*

By W. C. GORGAS, M.D.,
MAJOR AND SURGEON, U. S. A.

In this article I do not propose to discuss the general methods of sanitation used against yellow fever in Havana, as regards mosquito killing, but simply those methods which were used there in relation to quarantine.

Havana is situated in a deep, land-locked harbor, on the north coast of Cuba, just within the tropics. It is a city of 275,000 inhabitants, and has an extensive commerce with all parts of the world.

Yellow fever has been endemic in this population since the year 1762, not occurring, as it does among us, epidemically, but being always present. Every year and every month some deaths occur from this cause. In the mortality tables of Havana it is always present, being one of the principal diseases causing death in that locality. It occurs there as pneumonia or typhoid fever does with us, and in every case of fever occurring in one subject to the disease the possibility of yellow fever has to be considered by the practitioner. The profession for the past generation has pretty generally accepted the fact that yellow fever is not directly transmissible from person to person; but it was generally believed that the disease was due to some microorganism which escaped from the body, and underwent some further development outside the body, and then became capable of causing the disease in a fresh subject. In other words, that a non-immune person might very safely nurse a person with yellow fever, provided the sick man were placed in a new, non-infected locality. But if the patient remained in the locality in which he contracted the disease, then the non-immune nurse might very probably contract it also. It was believed that he did not contract it from a sick person, but from the infected surroundings from which the sick person originally contracted it. It was also known that when a sick person was taken to a non-infected locality, within a longer or shorter period this locality itself would become infected and give the disease to non-immunes living there. It was also considered as proved that the microorganism could be conveyed as a fomes, from an infected to a non-infected locality, in clothing and articles which had become contaminated by the sick person, and spread the disease.

Upon this theory it is evident that, if the microorganism can be kept out of a locality in which it

*Read at the Conference of State and Provincial Boards of Health of North America, held at New Haven, Conn.

does not exist, yellow fever can be controlled in that locality.

With the object of excluding the infection of yellow fever, quarantines have been very generally resorted to, and have generally been enforced by keeping out people sick with yellow fever, and by holding all non-immunes coming from an infected point five days from the time of their last exposure to infection. The period of five days was fixed upon as being, with a very few exceptions, the limit of the stage of incubation.

To prevent the introduction of infection which existed outside of the human body, various systems of disinfection of ships and fabrics have been resorted to. On the whole, these measures have been fairly successful; for though, in spite of quarantine, yellow fever has been time and time again introduced into our Southern cities, yet since the establishment of quarantines the frequency of its introduction has been greatly decreased.

Havana had been so generally infected with yellow fever that very little thought or attention had been given to preventing the infection being introduced there from the outside. This was the condition during 1899 and 1900. With cases occurring in every part of the city, and in every month, just as tuberculosis and bronchitis occur to-day in New Haven, there is very little use in going to large expense in trying to keep infection from being introduced from the outside. But, knowing that it was a communicable disease, very vigorous attention was given to quarantine of the individual cases within the city. As soon as we took charge in 1899 orders were issued requiring that yellow fever be reported to the health authorities by the physicians seeing the cases. Every effort was made to see that this was carried out.

As soon as the case was reported, if not sent to the hospital, it was strictly quarantined. Trusted guards in the employ of the Sanitary Department, in eight-hour shifts, were placed over the rooms quarantined, and nobody was allowed to pass, except the physicians in attendance. After the case came into the charge of the Sanitary Department nobody was allowed to leave the quarantined area for any cause whatever, and no one, except the physician, was allowed to enter it. On the termination of the case all fabrics of every kind which might act as fomites were taken to a central station, at Las Animas hospital, and were sterilized in a large steam sterilizer with steam, or, with formalin, as was thought best.

The quarantined area was then carefully scrubbed with a bichloride solution, 1 to 1,000, and sprayed everywhere by a force pump with the same solution, and then the rooms were closed and sealed, and disinfection with formalin, at the rate of 1 liter to 1,000 cubic feet of air space, was made, and the rest of the house well scrubbed and cleaned with soap and water, and afterward sprayed down with a bichloride solution of the same strength.

Early in 1901 the members of the Army Board put forward the theory, which they had demonstrated, and which Dr. Finlay had for the past twenty years maintained, that the mosquito was the means by which yellow fever was conveyed from patient to patient, and the only means, and that the disease was not conveyed by fabrics and articles soiled by the yellow-fever patient. As a result of the acceptance of this theory by the Sanitary Department the latter had to make changes in the quarantine regulations. If the disease could be transmitted from a sick person only by a mosquito, there would be no occasion to give any care to the bedding, fabrics, etc., soiled by the sick person, or coming from the infected locality.

In accordance with this view, the quarantine regulations of the city were modified. When a case was reported as yellow fever, the quarantined area was at once screened at public expense, with the idea of keeping infected mosquitos in, and of keeping out all mosquitos that had not been infected. A guard, as formerly, was placed over the quarantined area to see that the screen door was kept closed. A limited number of immunes, six or eight, were allowed to be designated by the physicians in charge, who could have access to the quarantined area.

When the case terminated, all the mosquitos were killed by fumigation with pyrethrum powder, but no attention was given to clothing, fabrics, etc. This lightened the irksomeness of the quarantine, and was a distinct advantage in getting cases reported.

This, to my mind, is a very important element in all measures of this kind, namely, to give as little inconvenience as possible. It is so important in all quarantinable diseases, and particularly in yellow fever, to have all cases reported, so that they can be properly attended to, that we gave this phase of the subject much consideration there. It is better in enforcing quarantine regulations to enforce a less effective measure, which causes less inconvenience, than to push a quarantine regulation which causes a great deal of inconvenience. And I very much doubt whether in a community of any size, even with power and unlimited means, harsh measures can be enforced with any certainty. If it is an attempt to keep people in or out, if the measures are too rigid and the necessity for the person's going in or out is sufficiently great, someone will find the means of getting through. In Havana, in fumigating for yellow fever, we used pyrethrum powder, for the reason that it was not objectionable to the people whose premises were being fumigated. It is a poor mosquitocide, and does not kill the mosquito with any certainty. In every fumigation a considerable number will be found merely intoxicated, and will revive if given access to fresh air. Sulphur, tobacco, and other substances are very much more deadly to the mosquito, but we feared that if we caused the people too much inconvenience by our measures it would result in cases being concealed, and the concealment of cases would certainly defeat the success of our work. Believing that the infection was carried only by the mosquito, and that microorganisms which escaped from the body of the sick person in any way, and were preserved in the clothing and fabrics around the room, could do no harm, we left these things alone. At the termination of the case the mosquitos in the house and in adjoining houses were killed; the screening was taken down and the guards were withdrawn. This was the plan of quarantine put into effect with regard to cases occurring in the city.

But other sources of infection had to be considered. The 200,000 Spanish troops, all non-immunes, who had been sent to all parts of the island for the three or four years previous to our occupation, had infected all parts of Cuba. In normal times the towns in the interior of Cuba are not subject to yellow fever, as a general thing. It is confined principally to the sea-coast towns, and quite generally persons from the interior are looked upon as non-immune and considered subject to yellow fever. Towns however, in railroad communication with Havana, even when situated off the coast and well in the interior, have been quite generally subject to yellow fever. Every few years yellow fever would be introduced from Havana and a local epidemic occur. Around Havana, within a radius of twenty

miles, are quite a number of considerable towns, which are practically suburbs of the city. Quite a large proportion of the population does business in the city, coming to town in the morning and returning in the afternoon. In these towns yellow fever was kept up by yearly importation from Havana. In 1901 our mosquito work reversed these conditions. By June we had gotten Havana free from yellow fever, while these little towns around and other parts of the island were having it as usual, and the question was at once forced upon us as to what measures we should take to keep the city free from reinfection. On the water side, with regard to infection from outside the island, the city was protected by a quarantine enforced by the Marine Hospital Service. The regulations and measures adopted by them were the same as those still in force, looking to fomites as the means of the propagation of the disease. On the land side, the city did not interrupt communication. We were acting under the belief that the mosquito was the only carrier of the disease. We, therefore, did not raise any questions with regard to the importation of fabrics or merchandize of any kind, but merely wished to keep those sick of yellow fever out of the city, and to keep persons who had contracted the disease from developing it in the city. Every railroad leading from Havana had one or more infected towns upon it, and as several of the towns were only from twelve to twenty miles off, connected with Havana by excellent dirt roads, it would have required a cordon of guards completely encircling the city on its land side to have insured non-intercourse, and would have, besides, completely paralyzed business.

We, therefore, after much thought and discussion of the subject, determined to adopt a system of inspection similar to the English system for Great Britain with regard to cholera. The object of our measures was to stop anyone actually sick with yellow fever from coming into Havana and to observe all non-immunes coming from infected points until the period of incubation was past. In this way we hoped not to have anybody in Havana sick of yellow fever for more than twenty-four hours without the fact being known, and, by promptly isolating the case and killing the mosquitos in the neighborhood, to prevent any injury being done.

With this object, a medical inspector was employed in each of the infected towns, whose duty it was to notify us by telegram of any non-immune coming to Havana. For this purpose we always employed a physician of the infected town, as he would be more likely to know the people personally, and have a general idea of who were immune and who not. Most of the infected towns were small towns; the largest, Santiago de las Vegas, has a population of 5,000 inhabitants, and of these 5,000 only 475 are non-immune. So that it was fairly easy work for a medical man, resident in the town, with three or four guards, to keep us informed of the non-immunes who came to the city, although communication was very frequent and close. We also had medical inspectors coming in on every train into Havana, and on all the roads leading out of infected towns. But these inspectors interfered with ingress into Havana only enough to get the names and addresses of the non-immunes coming into the city. Baggage, bedding, and traffic were not interfered with in any way nor inspected. The inspectors and guards about the infected towns, as I said above, were always selected from old residents of these towns. The inspector on the trains, by inspection of tickets, could get a fair idea of whether or not passengers came from infected points some distance away, and, unless he could satisfy himself that they were immune, they were treated as non-immunes. These reports came in during the day by telegram to the central office, giving the names and addresses of the non-immunes visiting the city. A medical inspector was at once sent to the residence of the non-immune, who saw him and took his temperature once in every twenty-four hours while he remained in the city. It would, of course, have been a great saving of expense to the department to have had these non-immunes report to us at some central point for examination, but we had so much at stake, and it was so important to us to get hold of all infected persons that we wanted to make the system as easy as possible for the people concerned, so that there would be no object in taking trouble to avoid the inspection. People who gave wrong addresses were reported to the police authorities in Havana, and if not found in Havana by the police were certainly caught when they returned to their small communities. A few sharp punishments sufficed. It was very much easier to comply with the regulations than to go to any trouble to avoid them, so that very little attempt at non-compliance was made on the part of those concerned, and a very general compliance with the regulations was soon obtained.

During the winter this same system of inspection with regard to non-immunes coming from infected points by water was kept up. In the fall the Marine Hospital Service took off their quarantine, but as a very sharp epidemic was present in Vera Cruz all through the winter, and was on the increase during the spring, the military governor issued an order putting the same system into effect, as far as Havana was concerned, on the water side. And this was kept up until the Marine Hospital Service again established their quarantine in the spring.

From the time the system was adopted up to the end of the year we had reported 1,250 non-immunes coming from infected localities. Among this number twenty-seven were discovered to have yellow fever, or developed it within the period of incubation. This seems to me a very satisfactory showing for the system, and it could hardly have been put to a more severe test.

After the middle of May our work had freed Havana from yellow fever, and we went from the 8th of May to the 1st of July without a case. In July we had four cases; in August, eight cases, and in September, six cases. In August quite a number of cases came from one locality, this locality being apparently infected. As fever was rife in Santiago de las Vegas and other suburbs at this time, I am inclined to think that the infection came from Santiago de las Vegas; that from some imperfection in the system a very mild case was overlooked by the inspector. But, of course, it could be even more readily explained on the theory that the mosquitos were left over from the cases that occurred in May, or that it had been kept up by one or two mild, unobserved cases occurring in the city during June. The test, however, could hardly be more severe, under any circumstances.

At the same time that we were freeing a city of 275,000 inhabitants from yellow fever, which had been constantly endemic for 150 years, we kept infection from being brought from half a dozen infected outside towns, without interfering in the least with traffic of any kind, or with passenger travel in any way. The non-immune population of Havana itself, at this time, was probably larger than it had ever been at any previous date, somewhere in the neighborhood of forty thousand. As far as yellow fever is concerned, I believe that the same

system could be adopted in communities where it is not endemic, but which are liable to epidemics of the fever. I doubt if, upon the whole, cases of yellow fever would more often get in than they do under our system of quarantine. The temptation is great, if the necessity is sufficient, for a non-immune to try to avoid the present quarantine regulations of the United States, and one unknown case in a non-immune community would be more dangerous than fifty known cases. And if even a case or two under this system escaped observation and developed a focus in a community, I would feel considerable confidence in being able to stamp it out by killing the infected mosquitos. Of course, it is important to have a good system of reporting so as to get hold of the first case and not let the infection spread, and in this it is very essential to have the sentiment of the community behind the health authorities. And with a system of mild quarantine and inspection such as we had in Havana in 1901, the authorities are much more apt to have the assistance of the people than when the quarantine measures are rigid and cause both great inconvenience and financial loss. In Havana there is no more objection on the part of the people to reporting a case of yellow fever than one of typhoid fever. It was much less inconvenient to report cases than to run the risk of the fine and punishment, which would be involved in not reporting, if discovered.

While a maritime quarantine against yellow fever, such as is enforced at present by our Marine Hospital Service, might be more easily kept up than a land quarantine, yet even the maritime quarantine, enforced by all the power and wealth of our federal government, is, at times, not sufficient to keep out the disease, as evidenced by the considerable number of times it has occurred in our Southern cities since that quarantine has been enforced. I think that, under the system of inspection, as enforced in Havana during 1901, yellow fever would no more frequently get into the United States than it has during the past years of rigid quarantine. The relief to commerce under such a system would be enormous. With our present knowledge and experience, I would, therefore, advocate as a quarantine against yellow fever, both land and maritime, that infected vessels, or vessels coming from infected points, be carefully fumigated, so as to kill all mosquitos in every part of the vessel. This would apply to ships on water and all cars, etc., on land. That the passage of merchandize, baggage, etc., be interfered with in no way whatever. That passengers, when sick, be quarantined and isolated; that all other passengers be allowed to pass freely; that non-immunes from infected points be seen once a day by a medical inspector, and if at the end of five or six days they are well, that they be released from all surveillance.

Is the Tendency to Contract Contagious or Infectious Diseases Greater in the Prisoner than in the Free Man?—Theodore Cooke says that having found that the previous history of the prisoner tends to decrease the power of resisting disease, as also do the loss of liberty, of outside exercise, and of friends and relatives, and having seen that the prisoner's regular life and prison discipline tend to rehabilitate this resisting power, and having found that means are employed to exclude infectious diseases from the prisons, it may be concluded that the danger of contracting infectious disease is not as great in the prisoner as it is in the freeman. While the prisoner, if left unprotected, like the freeman, would fall an easy victim to infectious disease, protected as he is from contact with the world, his liability to attack is not as great as it is in the freeman.—*Maryland Medical Journal.*

THE SURGICAL TREATMENT OF PUERPERAL ECLAMPSIA AND THE PREVENTION OF CONVULSIONS.*

By DOUGLAS H. STEWART, M.D.,
NEW YORK

PUERPERAL eclampsia has two causes: One intrarenal, due to diseased kidney. The other extrarenal, due to pressure upon renal veins, inferior vena cava, or ureters. Hindrance to their outlets increases the pressure within the kidneys, and "pressure urine" is not a true excretion, but a leakage containing a diminished amount of solids. This deficiency remains in the blood and becomes a circulating poison, composed of products which should have been cast out by organs at present inadequate to their work from interference with their drainage. This condition gives us the definition, viz., "puerperal eclampsia" is "a neurosis caused by the action of poisonous blood upon the nerve centers." Albumin is found in all forms; casts with organic cases and symptoms are a progress to convulsions, coma, and death.

An eclamptic woman's blood, with its decreased elimination, is progressively absorbing baneful waste from her body, her child's body, and from the meat she eats in the vain hope of "keeping up her strength." Her "strength becomes weakness" because all by-products remain in transitional states in the tissues of meat, and against all this absorption must be balanced the cleansing action of the monthly flow, which is here nil. The outlook is uncertain, as the maternal mortality is 30 per cent. and the fetal 50 per cent. Vigor and plethora mean peril. Weakness may be safe when strength has convulsions. Consumptives will sometimes undergo child-birth with an alarming amount of albumin. One case, in which four physicians, including myself, gave a fatal prognosis on urinary analysis alone, passed through an easy sixth labor, and after that lived some months. The autopsy showing pulmonary and renal tuberculosis. The latter causing the muddy-green, thick, and highly albuminous urine. The only noticeable point in her favor was that the abdomen was like a relaxed bag.

An early albuminuria foretells late hemorrhages, convulsions, and chronic nephritis. Should there be more than a faint trace before the third month, I think any obstetrician would be justified in terminating pregnancy. While willing to be corrected on this point, I wish to emphasize that albuminuria before the seventh month usually indicates post-partum danger, and in the last two months, trouble before or during labor. Sleeplessness or sleepiness are both of evil import. Vertigo, malaise, and the classics are purposely omitted. One woman that was blind for three days—and rather simple ever since—I have taken care of for almost seven years. The blindness soon passed away, but she had chronic Bright's disease before her pregnancy, and she has it yet. The other blind ones did well, and I am fast becoming of the opinion that only the untreated have amaurosis. At least, all that I have seen were more or less blind, and carrying dead children, when first visited.

In diet, have the patient avoid meat. Allow fish and chicken; but, with a free vegetable diet it will rarely be imperative to limit the food to milk alone. Impacted fæces will sometimes cause albuminuria, and one patient had convulsions. The impaction was spooned out and the bowel irrigated before the vagina would admit a finger, so great was the distension. After a complete house-cleaning, chloro-

*Read before the West End Medical Society, November 2, 1902.

form control was stopped and the albumin rapidly and progressively diminished. Normal labor took place more than two months later. One case had chorea in childhood and in adult life petit mal to this extent: She would stand still and drop anything in her hands The patient herself realized a connection between the attacks and some condition of the rectum. Albumin was present, also constipation and a rigid sphincter. Before any measure could be established, spontaneous expulsion took place. Some time after this the sphincter was stretched. I used nitrous oxide, but I never will again—not for such a purpose.

However, the point in question is this: The attacks were much benefited and the second pregnancy was without any abnormal incident. Of course, I do admit the possibility that the second labor might have been normal in any case—but the general improvement in the patient's condition after sphincter stretching was so great that I feel confident that sphincter spasm was the main element in this case.

In early traces of albumin and in irritability the urethra should be dilated to 32° F. This will often increase urinary flow. Obstruction in the female urethra is common, though generally spasmodic. In one case of convulsions with no albuminuria, after an irritable caruncle was removed with cocaine, the convulsions gradually ceased, though it was not until the day after operation that the last fit occurred and comfortable urination brought a calm confidence. I do not know of any attempt suddenly to occlude the human urethra, but if demonstrations on the lower animals are desired there are the reports of Lord Anson's voyages. The Chinese sold pigs by weight to the British ship *Centurion*, and obstructed the urethra to make the animals heavier by the retention in the bladder. Two-thirds of the pigs died before the ship was out of sight of land and were thrown overboard. The Chinese picked up the carcasses and later fed on pork. The death of the tortured animals was rapid and certain.

Inasmuch as we are dealing with a poisonous blood whose poisons would escape if possible, the simplest plan is to make a safety opening in the circulation. Having been in consultation and having met with bitter opposition, from physicians in charge, I have gone over a wide range in reading on this subject, and find my position well supported and that venesection is a preventive. It is curative, even its opponents admit, since there are fifteen recorded cases and one death. Blood-letting was the sole treatment, and this after convulsions had actually taken place.

If forbidding meat and freeing urethra and rectum does not lessen albumin we should draw off ℥ iv of blood. Follow that with a leech on alternate days. This is a working minimum. As I write, Dr. Dawbarn's remark on apoplexy comes to mind, "Don't bleed, the patient is going to need that blood later on. Instead cord the extremities, causing anæmia of brain and heart." This marks a difference at once. The doctor was speaking of healthy blood—the blood of life. In eclampsia we have a toxæmia—the blood of death—and the patient and her child are not "going to need" any stronger solution of poisonous ptomains, which is what we may expect "later on." Consequently dilute with the normal salt solution in the bowel and diminish the dangerous accumulation in the blood vessels by letting some of it escape.

The pulse jumps in nephritic cases, is heavy and full in those due to pressure. Bleed till the tension comes down, and albumin, swollen feet, headache, and disturbances of sleep will be relieved. In a case small bleedings, begun on October 5, 1902, with albumin 50 per cent. by bulk, lessened the amount to 5 per cent. by October 10. (Forty-six ounces being taken in all.) Every symptom had improved, the benefit to the mother was frankly admitted, notwithstanding, and in face of all argument, the attending physician terminated the pregnancy. He was afraid the child might die. It did not, even though put to the breast immediately after delivery. This leads me to think that venesection probably cleared the mother's milk of its poison.

Frequent small blood-letting is not depressing, on the contrary it removes a depressing poison, and it stimulates the blood-making organs to such a degree that many physicians express surprise as the patient becomes less anæmic. Any old German "barber-bleeder" knows that his customers are regular in attendance on his ministrations. As one expressed it, "when people begin to be bled they form the habit of getting full of blood and then they can't stop."

Watery loss can be made up by rectal irrigation, and the Kemp irrigator served me so well in one bad case that hereafter there will always be an instrument in my kit. The action of enteroclysis and the prompt absorption, diuresis, and diaphoresis is an immense subject, and Dr. Kemp has kindly consented to be present and to discuss this portion of my paper, therefore I merely say that with diet, fresh air, exercise, frequent small venesections, a free urethra and rectal irrigations we may eliminate the causes, and I almost believe puerperal eclampsia need occur only in neglected cases.

In an emergency, if convulsions have already taken place, my method of inducing labor differs a little from the ordinary. First, there must be progress all the time. Dawdling is distressing to relatives and dangerous to patient and child. Labor is most wearing and uncertain. Ignore pains and they seem to aid you. Depend on them and they will balk you. Discard them entirely and go safely. Advance slowly, but advance positively. Accouchement forcé is dangerous, but laissez faire is disastrous. I have only seen three absolutely untreated cases—with three deaths. Untreated means that ergot was administered by a midwife, but no other treatment. I think entirely spontaneous cases might do better.

There will be some cutting pains, as a rule, and we can make everything decidedly easier by the anæsthetic properties of carbonic-acid gas. A vaginal capsule with grs. x sodæ bicarb. and grs. v acid tartaric is convenient. This, in the cul-de-sac, seems to soften the cervix and relieve dilating pains better and quicker than chloral given internally. If the patient is to walk about, a wad of cotton with a thread attached will hold it in place, but should not be packed in tightly, nor with any idea of confining the gas, which begins to form in a few minutes. This simple appliance will be appreciated by physician and patient, especially as eclampsia cases are usually timid primiparæ. If then premature labor is imperative, introduce your catheter, then the capsule. Repeat capsule every two hours or oftener, follow it one hour after insertion with a heaping teaspoonful of sod. bicarb. and an even teaspoonful of lysol to the quart of water at 106° for a douche. When the cervix is large enough use the rubber bag dilator, if necessary to hasten dilatation; hang artery forceps or a light weight to the stem. A light constant pull aids very much. When dilatation is complete, if the labor pains then present are not strong, rupture the membranes without delay. A lacerated cervix that you may not get is far better than a convulsion which is always just at hand. Use the forceps dynamically, *i.e.* apply them and leave them alone for a quarter to a half hour; you will sometimes find traction unneces-

sary. Perhaps one blade would be easier to introduce, but I always have used both. When the anæsthesia is obstetrical or less, or when no chloroform has been used, the stimulant effect of the mere presence of the forceps is often very remarkable. Within a month I was consulted in a case. The attending physicians dilated the cervix fully with Barnes' bag. They waited five days more for rupture of the membranes, the ordinary baffling pains giving false hopes of beginning expulsion. The amount of anxiety and "sitting up all night" can be imagined. The mother and child were submitted to the well-known risk of prolonged labor—luckily no convulsion occurred during the long wait, and the family had not the slightest idea of danger. In their opinion "nature was simply taking its course." The attendant soothed alarm by saying he "could not take the baby because it would not live if he did." The fact being, as you all know, the longer the uterus remains unemptied the greater the mortality of mother and child. This mother is passing albumin up to date. The child is doing fairly well.

Two peculiarities of puerperal eclampsia need explanation: (1) It is most common in male pregnancies, this is attributed to the larger size of the male head. (2) It is most common in first pregnancies, here "my own," and, so far as I know, my unsupported theory is that the reason is purely mechanical and a question of intensity of pressure. The anterior abdominal muscles, the rectus especially, are more unyielding and furnish a stronger brace, for the uterus to push against, than those same muscles can when they have been stretched, thinned, and ironed out, as it were, by repeated pregnancies. Expansion of the uterus, resisted by well-developed anterior abdominal walls, will cause a harder squeeze tc any structures nipped between that uterus and the unyielding posterior walls. The pregnant uterus in the mother of many children is more globular and its upper level is lower than in a primipara wher it is being molded into an elongated shape. Such molding and elongation may result in severe "pressure-renal" symptoms. In primigravida are found a total of the many cases that arise through pressure on veins and ureters plus the few from intrinsic kidney disease. In multigravida pressure is more or less abolished by the relaxed abdominal wall, and these are the cases to which the knee-chest position does so much good. Nearly every one present has been or will be asked the question "Why should such a strong healthy girl have the second most alarming complication in obstetrics?" The form may be changed, but not the idea, for the sequelæ seem to cover the specialties. Blindness, deafness, œdema-glottidis, dislocation of shoulder and insanity being a wide range. One man met the more serious question of how "a magnificent specimen of girl-athlete" died with her premature child between breakfast and luncheon, the convulsion that took place proving rapidly fatal. That never occurred to me, but I know the details. On that occasion it first came to me that no case of early albuminuria, in a robust woman, should be allowed to pass the fifth month of pregnancy, and years have only confirmed the opinion that if trouble is present before pressure begins, in a muscular primipara, there will be death when damaged kidneys are squeezed later on. The cases without albumin are about one in ten. So that while albumin is positive its absence is not positively negative. But there is always deficient elimination, and two facts are common—(1) 90 to 96 per cent. occur in primipara, and (2) 66 per cent. are male pregnancies. The elasticity of the normal rectus aldominis is notorious and, perhaps from a purely speculative standpoint, section of the pyramidales might be considered, inasmuch as these are tensors of the linea alba. Experiment is necessary here as well as in multiple partial cutting of the rectus. At present it is easier and safer to remove pressure by emptying the uterus. In the quadruped gravity offsets the elasticity of the rectus, and I have vainly endeavored to find some record of one single case of puerperal eclampsia in the horse or cow. They do have renal diseases, but I would be very grateful for the details of even one case of puerperal eclampsia. Eclamptics bear pain well, but not sudden or unexpected pain, and in all cases shock is dangerous, as convulsions may be started by a slight noise. Spontaneous embryonic miscarriage is apt to be "incomplete." Make a pad of iodoform gauze over cul-de-sac and cervix, then introduce a Gariel balloon pessary and inflate. This is easier than tamponnement, and the whole contents of the uterus will come away with unruptured membranes. Possibly a dilating bag would answer.

In conclusion, let me add that Alfred Wiltshire, physician-accoucheur at St. Mary's in London, hits the key-note of venesection when he says: "The age of the patient must be taken into consideration." It is my own opinion that pulse is the guide to quantity and age to advisability.

Considering, as I do, the wedge-like action of the expanding pregnant uterus, flabbiness or firmness of abdominal muscles seem the keys to the problem of life or death for the fœtus in the interest of an eclamptic mother, and carrying the theory of an elastic "rectus" to an extreme point, I wish to indicate that when that elasticity is lost by repeated internal pressure we have one of three things: (1) The necessity for an abdominal supporter; (2) a larger child, or (3) chronic polyhydramnios. The frequency of the last in multigravida about equalling the frequency of eclampsia in primigravida.

121 West Eighty-eighth Street

HYPERTROPHY OF THE LYMPHOID RING OF THE PHARYNX AND ITS SURGICAL TREATMENT.

By H. HOYLE BUTTS, M.D.,
NEW YORK.
SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (THROAT DEPARTMENT); FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, ETC.

The subject presented for consideration is a broad one, inasmuch as it includes the hypertrophy of the lymphatics forming the structures known as the pharyngeal, faucial, and lingual tonsils. Although it is customary for teachers to subdivide these three conditions, it appears to the writer that they can be advantageously grouped for the moment, for general discussion, as they are histologically, pathologically, and clinically very similar.

These hypertrophies surround the region of the pharynx, with which you are familiar as the musculomembranous pouch situated back of the nasal cavities, mouth, and larnyx, extending from the base of the skull to a point opposite the sixth cervical vertebra, where it becomes continuous with the œsophagus. It is about five inches long, and is narrower below than above. It has four coats—an external fascia; a muscular layer, consisting of the three constrictors, together with the stylopharyngeal and palatopharyngeal muscles; a fibrous connective tissue layer, and a mucous membrane, extending to the base of the uvula, that is covered in its upper part with columnar ciliated epithelium, in its lower part with stratified epithelium. Mucous glands and lymphatic follicles are very abundant in the mucous membrane.

It remained for Waldeyer to bring to our attention

the close relation borne to each other by these lymphoid formations of the pharynx, and for Harrison Allen to describe satisfactorily their minute structure, which he did, in 1891, in the following manner: "The tonsil is an association of *diverticula* developed from the epithelial layer of the mucous membrane, in the walls of which are grouped *mucip-arous glands* and *lymph-follicles*. Resulting from this association, the tonsil is marked by the mouths of the diverticula, which open in a uniform manner upon the surface of the mass. The various tonsil groups differ from one another only in the arrangement of the diverticula. Thus in the lingual tonsils they are single, in the masses occupying the faucial spaces and the roof of the pharynx they are compound."

It should be borne in mind that in infancy and youth up to the age of fifteen years the normal mucous membrane of the pharynx is very rich in lymphatics. If these lymphatic structures have undergone hypertrophy they become of great importance from the effect they may have upon the general health and the special sense of hearing of those who are so affected. The faucial and pharyngeal tonsils are most frequently the seat of hypertrophy in childhood, and, because of the tendency of these structures to atrophy as adult life is reached, the family doctor is often guilty of advising against any operative interference, contending that the condition is one that will be outgrown. What is meant by the "outgrowing" of these conditions is that at times the lymphatic hypertrophies become absorbed, leaving behind only the increased fibrous tissue deposits, and as relief from some of the symptoms is obtained the inactive plan of treatment thereby appears to be justified.

The fallacy of the reasoning of those who advise time only as a remedy is proven by the fact that great and irreparable injury is being wrought to the general welfare and powers of hearing of the subject while waiting for this most indefinite result.

Hypertrophies of the lymphoid tissues of the pharynx are, as a rule, the results of catarrhal inflammations of the membranes, due to repeated attacks of colds in the head, or to inflammations of the pharynx accompanying scarlet fever, measles, or diphtheria. Several authorities claim that some of these hypertrophies are congenital, and there seems some foundation for the belief, as it is not an uncommon thing to find an infant one month old who cannot nurse at the breast on account of a hypertrophy of the pharyngeal tonsil; the writer has witnessed such a condition in a child three weeks of age.

Having considered lymphoid hypertrophies of the pharynx in a general way, we will proceed to take up the individual groups according to their location.

Hypertrophy of the Lymphoid Tissue of the Vault of the Pharynx.—Under this heading we will consider the well-known pathological condition, popularly called "adenoids of the vault," and more correctly described as a hypertrophy of the third, or pharyngeal, tonsil. There can be no question but what the term adenoids is a misnomer, is misleading and unscientific, as it indicates a tumor that has sprung from a gland, but long usage has made it acceptable as being descriptive of this lesion.

Thirty-four years ago an article, written by Wilhelm Meyer of Copenhagen, was published on the subject of adenoid growths of the nasopharynx, and it immediately challenged the attention of the medical world. It has frequently been stated by various authorities that the thesis was one of the most important ever contributed to this branch of medicine, as it was so thorough and accurate in its treatment of a new disease that little of value has been added to it by the hundreds of writers who have since discussed the subject.

In order to appreciate what constitutes a hypertrophy in the vault of the pharynx, it is necessary for us to determine the amount of lymphoid tissue present under normal conditions, which can be seen with the aid of the post-rhinoscopic mirror. Examination of the vault usually reveals a mucous membrane, studded with follicular openings and divided into four short, longitudinal folds, the outer ones of which are known as the lateral, and the central ones as the median folds of the pharyngeal tonsil. In contrast to this description of a healthy membrane we have the picture of one that is covered with grayish, stalactite-like projections, that may fill the entire postnasal space and even extend below the free margin of the velum palati. Hypertrophy of the pharyngeal tonsil is a condition that manifests itself principally in the first fifteen years of life, as during that period the lymphatic system is most active in its functions, and because the cavity of the nasopharynx has not reached its full development.

The diagnosis of a typical case of hypertrophy of the pharyngeal tonsil is a simple matter to one who has ever seen a child suffering from this disease, and who has studied its history. The guardian of the child will tell you that the little one has its mouth open and snores loudly at night, that it has great difficulty in breathing, and at times becomes bathed in perspiration in its efforts to obtain enough air while sleeping; that it has a cough; is subject to attacks of croup and nightmare; that there is a loss of appetite and a general lack of interest in the things that usually appeal to one of that age, and that the child is backward in its tasks at school.

On inspection of the child it will be observed that it is anæmic in appearance, a mouth-breather, has a vacant expression of face, a discharge from the nostrils, and may be stunted in growth and pigeon-breasted; in speaking, the voice has a muffled sound, and the hearing powers may be defective. When an attempt is made to examine the postnasal region with the mirror through the oropharynx, small patches of hypertrophied lymphoid tissue may be noticed on the posterior wall of the pharynx, and as the subject, if a small child, usually gags and contracts the velum, a mass of thick, viscid mucus will be seen to be forced down from behind the soft palate.

It is to be understood that the rather terrifying description just given does not apply to all cases, but such a combination does frequently exist. The ordinary case of adenoids will exhibit enough of these signs and symptoms to make one suspect their presence, which can be verified by a digital examination if a view with the rhinoscopic mirror is found to be impossible.

A digital examination of the nasopharynx should be conducted as follows: The child standing on the floor is closely pressed to the examiner's left side, and is instructed to open the mouth, when the examiner places his left index-finger across the left side of the patient's face in such a manner as to push the inner side of the cheek between the two rows of teeth. The index-finger of the examiner's right hand is then quickly passed up behind the soft palate and into the subject's pharyngeal vault, and swept around to ascertain the amount and location of the growths. If this method of examination is followed there is no danger of the explorer's finger being bitten, and an accurate knowledge of existing conditions will be gained without causing any real pain to the patient.

If the growths are present they may be recognized by contact of the finger with a soft velvety mass, filling up a part or the whole of the space, and bleeding easily on pressure. Adenoid vegetations

have been said aptly, but perhaps inelegantly, to feel like a bunch of worms.

There should be no two opinions regarding the method of treating hypertrophies of the pharyngeal vault. It is conceded by all high authorities that they should be thoroughly removed by surgical methods as soon as they are discovered to be a disturbing factor in a child's development. Having decided to operate in a given case, we are now face to face with the problem as to whether a local or a general anæsthetic should be employed, and as the writer has very decided views on this subject he will express them:

As a rule, it may be said that a general anæsthetic is required in all cases of removal of adenoids from the pharyngeal vault when the patient is under fifteen years of age. Rare exceptions may be made to this when the child has a small and well-defined group of tissue that can be located exactly with the mirror and when the operator feels certain that he can remove the whole mass with *one* introduction of the instrument. In such a case it is sometimes justifiable to do the operation under cocaine anæsthesia. There is one other occasion that can be recalled that should indicate an operation without a general anæsthetic, or, in fact, an anæsthetic of any sort, and that is in the case of an infant a few weeks old, who is unable to feed at the breast on account of adenoids blocking its nasal respiration. Such cases are frequently seen in the clinics, and relief is afforded by passing the forefinger up into the postnasal space and by means of the finger nail quickly breaking up the very soft and friable tissue found there. This method does not aim to be a complete and radical one, but it is intended to afford temporary alleviation until the child is sufficiently old to withstand the effects of an ether operation.

It will be seen, by glancing over the literature of the last ten years, that there is a steadily-increasing sentiment in this country in favor of the employment of general anæsthetics for operations of this nature. Articles by such well-known writers as Delavan, Knight, French, Wright, Chappell, and Hopkins lay great stress on this particular point, not alone for the sake of thoroughness in the operation, but in the interests of humanity and decency.

It is difficult to imagine a more brutal scene than that presented by a child struggling in the grasp of an assistant, with its face covered with blood, and the screams of pain and terror audible for a long way off, while the operator endeavors to regain an entrance into the vault with his forceps or curette. It may be said here that the success of an operation for the removal of adenoids depends largely on the thoroughness with which it is done, and we sincerely believe that a radical extirpation of these growths cannot be accomplished on a child who is frantic with pain and fear.

There is no greater mistake possible than to believe that a removal of a part of the offending mass will cause the rest of it to disappear by atrophy. Even with the most careful operators recurrences of adenoid growths do occur in about 1 per cent, of their cases, and this, too, in spite of the fact that the children have been under complete control at the time of operation, by the employment of chloroform or ether.

Some authorities claim, and without reason we believe, that if an operation has been thorough and the enlarged lymphatics have all been removed, that there can be no recurrence of the condition. This theory seems absurd when it is considered that groups of lymphatics other than those originally involved may become, later on, the seat of hypertrophic changes.

In a period extending over twelve years in the Manhattan Eye and Ear Hospital, during which from one to half a dozen cases of adenoids were operated upon daily under ether, making a total number of several thousand operations, the writer has never witnessed an accident due to the general anæsthetic. The objection most frequently urged against general anæsthesia in these cases is the possibility of asphyxiation from blood or vomited matter finding its way into the larynx, and this fear would seem, in the light of experience, to be unfounded.

The method of preparation and operation for cases of this kind is as follows: The parent is instructed to give the child a light breakfast at 8 o'clock on the morning of the day fixed for operation, and to see that it has nothing else to eat before bringing it to the hospital at 11 o'clock. Six hours having been allowed for the digestion of the morning meal, the child is placed upon the operating table, and ether is administered until primary anæsthesia is induced. As soon as the reflexes have been abolished, the head of the patient is lowered and a Denhard mouth gag is inserted far back between the jaws on the left side, and the operator, standing at the right side of the patient, carries a forefinger into the vault of the pharynx to locate the tissues to be removed.

When a forceps is used to ablate the growth the left forefinger is kept in the nasopharynx and used as guide until the mass has been seized by the instrument (to eliminate any danger of injury to the other parts), when it may be withdrawn and the severed tissues brought away. The forceps should be re-introduced as many times as may be necessary to thoroughly destroy all traces of the hypertrophied tissues, and it will frequenly be found useful to employ a curette in completing the operation.

As soon as the operator is satisfied that his labors are finished, the child should be rolled over face downward, and such blood as has accumulated in the pharynx and nasal chambers is allowed to escape; meanwhile the patient has probably regained consciousness. The hemorrhage is quite brisk for a few minutes, but, as a rule, it ceases spontaneously. The patient is then put to bed for twenty-four hours, and kept quiet and on a fluid or semi-fluid diet for a few days.

In a choice of the many patterns of instruments devised for this operation, the speaker has a decided preference for the Brandegee forceps (which is an improved model of the one given to us by Gradle of Chicago), and for the curettes designed by Gottstein, when an instrument of the latter type is required.

While the operation of adenotomy is a comparatively simple one, it at the same time demands a considerable degree of skill and experience in order to bring it to a satisfactory conclusion.

Unfortunately, there have been recorded in medical literature a number of cases, perhaps a dozen, of fatal hemorrhage following this operation. On investigation, afterward, nearly all of these cases were found to be hæmophiles. In cases of persistent primary or alarming secondary bleeding it is usual to try and control it by injecting through the nose, by means of a syringe, a full strength solution of hydrogen peroxide, and if this fails, the nasopharynx should be tamponed with gauze.

A postnasal tampon is made by folding and refolding several times a piece of sterilized gauze into a compact body, sufficiently large to fill the vault of the pharynx. Around this tampon is tightly looped a piece of strong aseptic twine, that is about twenty inches long and has previously had its free ends tied together. In order to place this tampon in position, it is required that something flexible, like a soft catheter or a wire loop, should be passed through one

nostril down into the oropharynx, where it is seized by a forceps and attached to the string of the tampon. Traction is then made through the nose, and the tampon is drawn up into close contact with the bleeding surface, with the assistance of the surgeon's digital manipulation through the mouth. The free end of the string should then be secured to the patient's face by means of adhesive plaster, and the tampon allowed to remain *in situ* for several days.

Postnasal tampons sometimes fail to accomplish what is expected of them because they are not made sufficiently large to fill the space completely.

Hypertrophy of the Faucial Tonsils.—This is a condition so frequently met with in the general practice of medicine that but little need be said about its gross appearances.

Hypertrophies of these structures take place during infancy and childhood, and are intimately associated with the overgrowth of the lymphatics of the pharyngeal vault. In fact, it is the exception to find permanently enlarged faucial tonsils that are not accompanied by some degree of hypertrophy of the pharyngeal tissues. The causes producing hypertrophy of the lymphatics of the vault are identical with those affecting the growth of the faucial tonsils, except that the latter are placed in a more exposed position, and are subjected to the additional irritation caused by contact with food during the act of deglutition,

On examination of the oropharynx of a subject who has hypertrophied tonsils we will observe ovoid masses occupying the spaces between the anterior and posterior pillars of the fauces, which are of firm, fibrous consistency, and on their exposed surfaces present about a dozen openings of the diverticula already mentioned as existing in the normal tonsil. These masses may consist of one or two, and very rarely three, bodies, known respectively as the faucial, velar, and foliate tonsils. The faucial lobe is the one which we generally have to treat, as it is the main one occupying most of this region, and lies just below the small velar one; the foliate tonsil, which is ill-defined and infrequent, lies between the faucial tonsil and the palatoglossal fold. These subdivisions of the tonsillar mass are of practical value only in directing the attention of the operator to the possibility of his work not having been complete after the removal of the principal growth.

The injuries caused to a child's health by hypertrophied tonsils are much the same as have been already enumerated in the condition of adenoids of the vault, and as large tonsils are rarely found in the young disassociated with adenoids, the symptomatology may be described as similar, with the addition of more or less frequent attacks of sore throat.

At this late day it seems almost unnecessary to enter a plea for the total extirpation of these diseased glands, but one does occasionally meet a misguided parent who advances obsolete arguments for their retention. While we are free to admit that the physiology of the tonsil is not understood, we do know that the functions of this organ cannot be performed after it has undergone extensive pathological changes, and that its presence does invite contagion, and is a constant source of irritation to the surrounding mucous membrane.

The methods employed for the removal of hypertrophied tonsils are ablation with the tonsillotome, ignipuncture, the galvano-cautery loop, and the cold-wire snare.

In children there is only one method worthy of consideration, and that is by the use of the tonsillotome while the patients are under the influence of a general anæsthetic.

A child should be prepared for the operation, as has already been described when adenoids are to be removed. The speaker recommends the Mackenzie tonsillotome as being the safest and best instrument for the operation, and when it is properly used it will be found that the tonsil has been entirely enucleated.

The patient being in the primary stage of ether narcosis with the head lowered, a Denhard gag is introduced into its mouth between the jaws on the left side, and the anæsthetist places the palmar surfaces of his hands firmly over the external neck to give support to the region to be operated upon. The operator, standing on the right side of the patient, carries the tonsillotome into the mouth with his right hand in much the same way as he would introduce a tongue-depressor, with the flat surface down, until the opening in the instrument is opposite the left tonsil, when it is turned at right angles, and the mass will be felt by the operator's left forefinger, used as a guide, to be within the grasp of the instrument. The operator's left forefinger is then slipped back on the shaft of the instrument and used to exert lateral pressure, and the blade of the guillotine is then sent home by the thumb of the operator's right hand. The severed tonsil is then quickly brought out and disengaged from the instrument, and the latter is immediately re-introduced, but by the operator's left hand this time, when the right tonsil is removed and the operation is completed. The patient is then turned and kept on its side with the face downward over the edge of the operating table until the bleeding has ceased. If adenoids are present, the patient is then given more ether, and they are removed in the manner before prescribed.

The cardinal rule in removing tonsils with the Mackenzie instrument is the using of a sufficient force laterally to get the ring of the tonsillotome around the base of the growth, and in this the operator is materially helped by the counter-pressure of the assistant's hands. If at the time of the operation the anterior faucial pillar is found to be adherent to the tonsil, it may be freed with a bistoury, and when this has been done there will be no obstacle to the removal of the entire mass. Apropos of the use of force in doing a tonsillotomy there can be no better illustration than that given by Sir Morrell Mackenzie, the inventor of the instrument, who said that the best operator for this condition he had ever known was an assistant of his, who was so heavy-handed that he never could do any other surgical work successfully.

No injury can be done to the surrounding parts if at the time the cutting occurs the blade of the instrument is held in a vertical position.

The after care of the child is important in order to guard against the possibility of a secondary hemorrhage. Whoever is left in charge of the patient should be instructed to see that he is kept perfectly quiet for the succeeding twenty-four or forty-eight hours, and not permitted to use the voice more than is absolutely demanded. Profound sleep after ether narcosis should not be allowed for several hours, as there have been reported several instances of serious results, due to a return of hemorrhage, which remained undetected. Only cold, soft food will be found acceptable to the patient, and is all that should be given. Small pieces of broken ice, held in the mouth, will be grateful to the patient's lacerated throat, and tend to prevent a recurrence of the bleeding. After several days have elapsed a mild antiseptic spray will be found of service. These simple preventive measures, conscientiously fulfilled, will render the chances of a secondary hemorrhage infinitely small and insure peace of mind to all parties concerned.

A great deal has been written about the dangers of

hemorrhage following tonsillotomy, and in 1893 the speaker made it the subject of an investigation, and read his conclusions, at a meeting of the Section on Laryngology and Rhinology, of the New York Academy of Medicine.

Up to that time there could be found in the entire medical literature of the world only fifty reported cases of alarming hemorrhage following this operation. Two of these cases were fatal in results, and one operator, Broca of Paris, had the misfortune to have both of them occur in his practice during the year 1879. In one of the cases death was caused by severing an anomalous internal carotid artery and in the other no details were given.

As to what constitutes an "alarming" hemorrhage arising from the tonsils, no general precept can be laid down; each individual case must be judged in itself, therefore the amount can only be defined as relative. It may be stated, in a general way, that after the excision of a tonsil in a child, it is customary to expect bleeding, varying in quantity from one drachm to two ounces. If the amount more nearly approaches the maximum degree mentioned, it is usually quite brisk for two or three minutes, and then subsides altogether. If the operation has been conducted under the primary effects of a general anæsthetic, a certain proportion of the amount of blood already designated is apt to find its way into the stomach and be vomited later; this may excite apprehension on the part of the patient or his family, who fear that it indicates a return of the bleeding. They should, therefore, be warned of the probability of this event.

In looking over the literature concerning the checking of tonsillar hemorrhage, it will be observed that the whole gamut of styptics has been traversed, and very rarely, if ever, have any of these drugs proven of service, unless combined with pressure. The much-vaunted combination of tannic and gallic acids, three parts of the former to one of the latter, as suggested by Mackenzie, may be of some use to control capillary bleeding that would probably cease spontaneously in a few minutes if left alone. Certainly it could not be expected to seal the mouth of a spurting artery of any considerable size, that is surrounded and held open by dense fibrous tissue. As a rule, then, it may be said that these drugs are inadequate to the emergency for which they have been recommended. If the hemorrhage is really of a serious and dangerous character, then some surgical or mechanical interference becomes imperative to prevent exsanguination, unless by a happy chance the patient goes into a condition of syncope, when the bleeding ceases as the arterial tension is lowered.

In some few cases of serious hemorrhage, when the artery is exposed, simple torsion with the forceps is all that is required. Oftentimes, though, the walls of the vessel will be found brittle, or cannot be seized, and it will then be necessary to transfix the stump of the tonsil, if enough of it remain, with a needle, and surround the mass with a silver wire ligature. These two methods, with the use of the actual or galvano-cautery applied to the bleeding points, practically include all minor surgical aids. It has been quite thoroughly demonstrated that the ligation of either the common or the internal carotid arteries singly cannot be relied upon, so that the only hope in this direction is to tie both of these vessels, or the external carotid near its origin from the common carotid artery. The idea of tying one of the great vessels of the neck is likely to appear rather formidable to many, and justly so, if the same result may be attained with other means.

The general consensus of opinion on the subject of checking tonsillar hemorrhage convinces one that the simplest and most successful method has been that of direct pressure to the bleeding surface. Most of the mechanical aids to this procedure have been found faulty in contrivance, or impracticable for actual use, and the surgeon has been obliged to resort to nature's only provision for this unexpected event, to wit, the use of his fingers. It matters not whether the bleeding occurs from a large, spurting artery that has been severed in one tonsil, or is in the character of prolonged, excessive oozing from both sides of the fauces, he will be forced to introduce one or two fingers, of one or both hands, into the mouth, as the case may be, and keep up pressure with them until the result is accomplished. In a few cases with which the writer is familiar, this pressure has been required for several hours continuously; not a pleasant task, even when the operator is helped and relieved by competent assistants. At best, digital compression must be limited, uneven, and unsatisfactory, as the hands become tired.

To obviate this exhausting and indifferent method of checking tonsillar hemorrhage the speaker designed, some years ago, a tonsillar hemostat, which has been found to be an efficient substitute for the fingers. This instrument is readily placed in position, and its effect may be noted by the use of the head mirror, which is rather a difficult task when the patient's oropharynx is occupied by the surgeon's fingers.

In regard to the other methods for the removal of hypertrophied tonsils little need be said. The only time that they should be considered is when the subject is an adult well on in life, and has a comparatively small, white and indurated tonsil. Experienced operators have learned to approach a tonsil of this nature with considerable respect, and to exclude it from their cutting procedures on account of its liability to cause great annoyance by excessive bleeding. Such growths are best removed by the use of the galvano-cautery snare, as suggested by Knight, or by the cold-wire snare, as described by Farlow. Ignipuncture is a slow and painful method of destroying these tissues, and is rarely used except to comply with the wishes of the patient or his guardian, who has an objection to a cutting operation.

Hypertrophy of the Lymphoid Tissue at the Base of the Tongue.—This section of the lymphoid circle of the pharynx was, perhaps, the last to receive serious attention at the hands of the specialist, who devotes his energies to the diseases of the throat, but that his labors have been well rewarded cannot be doubted when the number of obscure symptoms that have been traced to this region are borne in mind.

It is interesting to note that while other manifestations of the overgrowth of the pharyngeal lymphoid tissues are those essentially of childhood, the condition known as an hypertrophy of the lingual tonsil is rarely encountered before mature adult life has been reached.

Hypertrophies at the base of the tongue are observed only by the aid of the laryngeal mirror, and they can be seen to the best advantage by grasping the tip of the organ with a napkin held in the examiner's left hand, and drawing it forward so that the anterior end protrudes from the mouth. This act provides sufficient space for the passage of the mirror, and enables one to inspect the region thoroughly.

Contrary to the teachings of most textbooks, which lead one to expect that the tongue on its posterior surface is quite smooth, there will be found numerous slight elevations commencing below the apex of the angle formed by the circumvallate papillæ. These elevations vary in size from those of the dimensions of the head of a common pin to those as large as a split-pea; they occur singly or in groups

and are sometimes sufficiently large and numerous to cover the whole base of the tongue. When the latter is the case the epiglottis will be found to be resting its anterior and lateral surfaces on the mass, or it may be partially buried in it.

Constant contact of the epiglottis with the base of the tongue serves to keep up an irritation of both of these organs, and is responsible for the train of symptoms that is referable to this region. Besides the hyperæmia of the mucous membrane covering the epiglottis, caused by the constant friction of the opposing surfaces, the numerous small plexuses of veins situated at the base of the tongue become permanently enlarged and form varices.

Hypertrophy of the lingual tonsil seems to be of greater frequency in the female than in the male sex, or at least women complain of trouble in this region more often than do men. This may be explained possibly on the basis of the former being of a more sensitive nervous type than the latter, as when we consider the additional irritation of smoking and chewing tobacco, drinking, etc., to which man subjects his throat it seems strange that he does not have more trouble at this particular point.

Patients suffering from this condition usually state that there is a constant desire on their part to swallow, in order to get rid of something that seems to be lodged in the throat; many of them have a well-defined idea as to what it is they are trying to dispose of, and variously claim that it is a crumb, fish-bone, "lump," or some other foreign body that causes a feeling of fulness in the lower pharynx; pain is an occasional symptom of this condition, and patients frequently complain of a burning sensation; those that use the voice very much for singing or other purposes say that it becomes easily fatigued and most unreliable, sometimes disappearing altogether.

The most marked and annoying symptom produced by hypertrophy of the lingual tonsil is, however, the racking cough that very often accompanies it. A cough of this kind is usually paroxysmal in character, and is most often present at night when the patient first goes to bed, although it may occur intermittently throughout the sleeping hours. It would seem as though this night cough could be explained by the gravitation of the tongue deep down into the pharynx, thus bringing the lymphoid mass into more intimate relations with the epiglottis, while the subject is in the recumbent attitude. Whether this theory is correct or not, patients state that the only relief they obtain is by a change in the position of the body, and then it is only a temporary one.

Patients become very much alarmed at times because of the appearance of blood in the sputum after one of these violent attacks of coughing; these hemorrhages are due, of course, to the rupture of one or more of the small varicose veins already mentioned as being found at the base of the tongue.

The plan of treatment for a reduction of the masses of lymphoid tissue found in this location that has been most generally approved is one of destruction by the use of the galvano-cautery. This is accomplished under local anæsthesia, a 20-per-cent. solution of cocaine being employed for the purpose, by means of a curved electrode having a broad, flat platinum tip, which is applied to the different prominences under the guidance of a laryngeal mirror.

In making an application of the galvano-cautery to the region of the base of the tongue it is well to have the coöperation of the patient, who, by retracting his own tongue, leaves the left hand of the operator free for the manipulation of the laryngeal mirror while he directs the cautery point and controls the current with the right hand. In using the cautery here great care should be taken not to scorch the epiglottis, as it is capable of getting up a very marked inflammatory reaction, and this can be best avoided by not turning on the current until the tip of the cold electrode has been buried in the mass that it is desired to destroy. Another point that is worthy of attention is not to do too much burning at one sitting; three applications of the cautery point is about all that a patient will submit to at one time, as considerable pain is felt then, and the wounds are sensitive for several days afterward, on account of the exposed position and mobility of the parts; an interval of a week's time should be allowed before repeating the cauterization, and this conservative policy should be pursued until the hypertrophies have been destroyed and the symptoms have disappeared.

The free use, at home, of an albolene spray, containing 3 per cent. of menthol, will contribute greatly to the comfort of the patient during the course of treatment, and by giving protection to the wounded tissues, hasten their resolution.

313 Madison Avenue.

A CASE OF SEPSIS, FOLLOWING AN ATTACK OF OSTEOMYELITIS FROM A SLIGHT CAUSE.

By SAMUEL KOHN, M.D.,
NEW YORK.

This case, from its apparently trifling inception to its fatal termination, five and one-half weeks later, was so abounding in interest, from both a diagnostic and a therapeutic standpoint, as to render the publication of its history obligatory.

Miss R. M., aged twenty-six years, born in the United States, unmarried, called at my office, in Arverne-by-the-Sea, L. I., Sunday, August 21, 1902, complaining of moderately severe pain, in and about the right wrist-joint, and gave this history:

On the day previous (Saturday) she had visited Sea Side, Rockaway Beach, with a number of her girl friends, for the purpose of seeing the sights; in the course of the afternoon she had taken a ride on the scenic railway, an elaborated toboggan slide, consisting of a number of ascending, as well as descending, grades, in consequence of which the motion of the car reached such great momentum at times that she was compelled, in order to steady herself, to grasp firmly the upright iron bar, a part of the car's construction. She stated that, in so doing, she felt at the time she was unduly straining the muscles and tendons of the right hand and wrist. Following this, she and her friends enjoyed a ride on one of the enormous carousels, in which Rockaway Beach abounds, and here again, in order to counteract the dizziness excited by the rotatory movement in one direction, she grasped with her right hand the iron upright nearest to her, holding on firmly as long as the motion continued. During the afternoon and evening she suffered from some pain in the right hand and wrist, but it was not until the following morning that she called upon me.

The parts about the right wrist were found slightly swollen; there was considerable tenderness to pressure; but, owing to the straightforward history of an unusual strain suddenly placed upon the muscles and tendons of the right hand and forearm, I experienced no difficulty in diagnosing an acute periarthritis of the wrist, and ordered several small ice-bags and absolute rest.

The following day I was called to the patient's home; found the wrist more painful to the touch; there was more swelling, and slight redness on both the extensor and flexor aspects of the joint; believing that synovitis had probably been superinduced

by the strain on the joint, I put the patient to bed, and ordered evaporating lotions of lead and opium. The temperature was at this time 102° F., pulse 80; otherwise the patient felt very well. On the third day the pain in the wrist became so intense that I was called at midnight, and was compelled, in order to allay the agony of the patient, to give three hypodermics, each of one-quarter of a grain of morphine, successively. The temperature was 104½° F.; pulse 90.

A thorough physical examination of the patient was now undertaken, to determine, if possible, the source of the severe infection, and of its results, if any. But a most careful and painstaking examination failed to reveal anything abnormal in the throat, lungs, heart, or abdominal organs; the sensorium was perfectly clear, the patient being only very much excited by the severe pain.

The salient and predominating signs and symptoms were to be found in the right wrist-joint. The previous history of the patient was carefully gone over with the mother, who assured me that, although her daughter had always been somewhat pale and slight of stature, she had not complained of being ill up to the day of her visit to Rockaway Beach.

From the patient I learned that for several days preceding the accident she had passed some blood per rectum and had suffered slightly from dysuria. This seemed to furnish a clue which might have led to the diagnosis of gonorrhœal rheumatism. I learned that she had been troubled for some time with bleeding piles. A vaginal examination was not obtainable, the patient absolutely refusing to allow any such procedure. As her menses appeared the following morning, I concluded that the bleeding from the rectum and the dysuria had probably been the forerunners of the monthly period.

Later on, in the course of the sickness, we had abundant opportunity to satisfy ourselves that the suspicion of a gonococcus infection was entirely without foundation in fact.

On this, the fourth day of the illness, the swelling and redness extended over the dorsum of the hand, and half way up the forearm. There was some swelling and redness on the flexor side of the wrist; extreme tenderness to the touch, diffused over the whole region; movement at the wrist was impossible because of the intense pain, the slightest movement of the fingers being exquisitely painful. Temperature, 103° F.; pulse, 84.

Salicylate of sodium was now given in gradually-increasing doses until saturation was effected, as evidenced by tinnitus, deafness, etc.; in the course of forty-eight hours she received the drug in fifteen-grain doses with one-quarter grain of morphine every two and one-half hours, while awake.

In spite of this medication, the temperature remained high, rising to 104½° and falling to 100°, twice in the twenty-four hours. The pulse at all times was fairly strong, regular, and, compared to the temperature, slow; ranging from 80° to 90°. No change was noted in the condition of the wrist. On the supposition that there might be a malarial infection, quinine was given in heroic doses, for several days, with no more effect upon the fever than if so much common salt had been administered. Iodides produced no more relief than the other drugs.

Of the local treatment, almost the same story is to be told. The arm was immobilized in a starch bandage on the third day, after the lotions and ice bags had failed to produce any amelioration. Owing to the severe pain, the bandage was removed the following day, and a 50-per-cent. ointment of ichthyol in lanolin, thickly applied; later tincture of iodine and blistering were tried successively, with the result of slightly alleviating the pain. On the eighth day auscultation of the heart revealed a slight, blowing systolic murmur, heard most distinctly in the third intercostal space, about three inches to the left of the sternum. It was audible at the apex, but slightly; was not conveyed to the vessels of the neck.

As this was the first discernible objective symptom aside from the wrist, since the onset, I determined to watch it carefully. The swelling and pain about the wrist had by this time somewhat diminished. It was possible for the patient to move the thumb and little finger slightly without pain. All other movements of the hand or fingers were still productive of great pain.

The exacerbations and remissions of fever every twelve hours, approximately, occurred regularly until the ninth day, when the patient had a slight chill in the afternoon, followed by a temperature of 105½°; which, in turn, gave way to a profuse perspiration, and a fall of temperature, within six hours, to 101°. On the tenth day another chill, more severe than the first, followed by high temperature, perspiration, and sudden fall of the fever to 99° F.

The following three days were comparatively comfortable, although the fever rose daily, as high as 103° F. The pain and tenderness in the affected wrist were becoming more localized in the articular end of the ulna, on its outer surface.

On the thirteenth day, at the patient's urgent solicitation, she was removed to her home in New York. Every precaution against jolting was employed, as the slightest jar conveyed to the forearm and wrist caused her to scream with pain. At this time Dr. Walter M. Brickner became associated with me in the management of the case.

A careful examination of the wrist now showed the point of greatest sensitiveness to be localized on the outer surface of the ulna, for a distance of two inches from its articular end at the wrist.

On September 16 Dr. Frank Markoe, who saw the patient with us in consultation, agreed that it was a marked case of sepsis, due probably to osteomyelitis of the lower end of the ulna, and that an operation might lay bare the source of infection. The results of the painstaking examinations of the blood and urine by Dr. Libman will be given below:

September 17.—The pain in the ulna still being very severe and the fever showing no signs of abatement, we concluded to operate. Dr. W. M. Brickner performed the operation.

The ulna was laid bare, and was found, at the point corresponding to greatest sensitiveness, to be denuded of periosteum, over an area of about half an inch square; the extensor tendon was deeply congested and soft. The tissues were soft and somewhat macerated in appearance; bleeding from the wound was so slight as to attract our attention. Probably due to thromboses of the smaller vessels. The ulna, chiseled open to its center, was considerably congested and softened, but no pus was found.

The highest temperature for the twenty-four hours preceding the operation had been 102.6°. On the following day, September 18, the patient had a chill, followed by a temperature of 105.6° at 10 p.m.; which by 7 o'clock A.M. on the 19th had fallen to 99°. The pulse throughout the illness had been of excellent quality and was so at this date, ranging from 80° to 100°. This feature, together with the absence of streptococci and staphyloccoci from the blood cultures, militated against our diagnosis of septic endocarditis. It seemed to us that an endocardial inflammation of a severity sufficient to produce such high temperatures must necessarily involve the muscular structure of the

heart to an extent sufficient to produce a rapid and feeble, or even an intermittent, pulse.

September 18.—The systolic murmur became more distinctly audible; a slight diastolic murmur was now heard, immediately following the systolic; this became more marked from day to day, until it became almost coequal in loudness with the systolic murmur. Both murmurs were heard with maximum intensity in the third left intercostal space, in a line with the left nipple. Examination of the abdominal organs revealed some enlargement of the liver, the free border being two finger-breadths below the free border of the ribs; the right kidney slightly movable. Dr. M. Manges saw the patient in consultation on September 18, and agreed with us in the diagnosis and treatment.

Frequent examinations of the urine showed slight traces of albumin, but no casts.

The treatment up to this time had included every possible means of combating sepsis; the nourishment of the patient was kept up to the highest point possible; when the stomach rebelled nutrient enemata were given at regular intervals, and were retained; stimulants, in the form of whiskey, Tokay wine, and champagne, were taken freely. High saline enemata and hypodermoclyses of normal saline solution were tried and found wanting.

Credés silver ointment was used faithfully and thoroughly for a period of several weeks without result. Marmorek's antistreptococcic serum was injected five times; after each injection the temperature rose within twelve hours to 106° or 106½°, and fell as rapidly from this to 99½°.

Hypodermics of pure carbolic acid were given for a time in two-per-cent solution; quinine and urea were used in the same manner, when the stomach rebelled against quinine. On the supposition that the infection might possibly have its source in the intestinal tract, salol and, later, guaiacol carbonate were administered for a time without any perceptible effect.

With all this, sponging with cool water was regularly resorted to when the temperature rose above 103°, and cardiac stimulants—strychnine or sparteine—were injected as required.

But, in pite of all these therap utie measures, the temperature continued to reach a height every day of 104° to 106° or 106½°, attended now and then by chills; and dropped as regularly to 99° or 100°. The patient's stomach throughout the illness has been, at times, rebellious, causing vomiting of the liquids ingested, but neither in the vomited matter, nor in the stools, was anything abnormal found, aside from some stringy mucus; no blood nor pus.

September 29.—Dr. A. Jacobi saw the patient with us, and agreed substantially with us in the diagnosis and treatment. From October 1 to October 8 the temperature ran the same course as in the preceding weeks, showing two exacerbations and remissions daily.

The wound in the ulra had almost healed; patient had for some time ceased to complain of any pain, and for two weeks had been able to move the hand and fingers. On October 8, at 8 A.M., the temperature was 105.4°, pulse 140°; patient had an attack of vomiting, fell into a collapse, and died at 11.30 A.M.

The extraordinary features of this case are:

First.—The production by such a trivial cause of an osteomyelitis, of sufficient virulence to produce a profound septic infection. It may, of course, be assumed that the infection took place through some unrecognized channel, previous to the accident—through the throat, the vagina, or a hang-nail, perhaps—and that the strain upon the structures of the wrist was the exciting cause which caused the cocci to settle in the ulna. But no lesion was found on the skin or anywhere else to account for such an infection. It may also be argued against the hypothesis of a pre-existing infection—would a young woman suffering with the symptoms of a systemic infection go out lightheartedly to see the sights, and take advantage of all the attractions of a seaside resort as this one did?

We learned after the patient's death that she had complained of a hang-nail on one of the fingers of her right hand shortly before she was taken sick; but had this been the point of entry for the infection would there not have been some symptoms accompanying it?

The only conclusion to be reached, therefore, is to concede the possibility of a severe muscular strain, inducing an osteomyelitis.

Second.—The existence of a grave septic endocarditis, evidenced by marked murmurs, attended by high fever, with a *good* pulse, *slow*—out of proportion to the fever, ranging from 80° to 110°—and perfectly regular. This quality of the pulse, together with the sterility of the blood cultures, seemed inconsistent with a serious endocardial and myocardial inflammation.

Third.—The exacerbations and remissions of fever, which took place *twice* in every twenty-four hours during the entire course of the disease, and the sharp and sudden declines; withal the sensorium throughout the disease was perfectly clear.

Fourth.—The complete failure of all therapeutic measures to influence, in the slightest degree, the steady onward course of the sickness; for five and one-half weeks the sepsis was fought at every step by every known means, but without any favorable result whatever.

Fifth.—The final interesting feature takes the form of a question. Was the lesion in the ulna a metastasis from a pre-existing infection which produced the endocarditis; or was the osteomyelitis of the ulna the primary of affection?

I incline to the latter belief.

REPORT ON THE EXAMINATIONS OF THE BLOOD AND ON THE POST-MORTEM EXAMINATION.—BY E. LIBMAN, M.D.

Examinations of the Blood.—On September 12 the count of the blood gave 10,000 leucocytes. Spreads showed a preponderance of polymorphonuclear leucocytes. No plasmodia were found, and the Widal-reaction was absent. A blood-culture was made, 10 c.c. of blood being drawn from one of the veins at the elbow. Both plates of serum-glucose-agar and flasks of glucose-bouillon were used. The result was entirely negative.

On September 13 the urine was plated. It was practically sterile, only one colony of the staphylococcus albus being obtained from 5 c.c.

The culture made by Dr. Brickner at the time of operation (from the bone) was sterile.

On September 23 a second blood-culture was made, using 15 c.c. of blood. The same media were used as before. In one flask there developed after two days, an organism subsequently identified as the staphylococcus aureus.

On September 24 the blood was again examined for plasmodia, with a negative result.

On October 4 the urine was again examined, but no colonies of the staphyloccus aureus were obtained.

Post-mortem Examination.—Performed on October 8, 1902.

Lungs.—Bilateral hydrothorax; congestion; slight œdema.

Heart.—All chambers dilated. No evidences of

old lesions. Anterior and left posterior flaps of aortic valve covered by friable vegetations. Vegetations extend to a slight extent over the endocardium of the ventricle. The sinuses of valsalva are filled by soft vegetations, and there is a perforation leading from them into the right auricle, just at the attachment of the tricuspid valve. The perforation on the auricular side is covered by a large mass of vegetations, which implicate the tricuspid flap by contiguity. There are no vegetations on the free margin of the valve.

The heart-muscle shows marked parenchymatous and some areas of interstitial myocarditis. An occasional area is purulent.

Liver.—Enlarged; congested; parenchymatous, and fatty degeneration; increase of periportal connective tissue; a hemorrhagic infarction in the right lobe, near the free border.

Spleen.—Very much enlarged; pulp congested, very soft (acute hyperplasia).

Kidneys.—Congested; marked degeneration.

Pancreas and Adrenals, Bladder, Uterus, and Appendages.—Practically negative. The *right ulna* shows a small granulating cavity at the lower end.

The gastrointestinal tract and brain could not be removed. No external portal for the infection could be found; abdominal and thoracic veins negative.

Bacteriologic Examination.—Cultures were made from the centers of some of the vegetations on either side of the heart, from the blood in either ventricle, and from the spleen. A few colonies of the staphylococcus aureus developed in all the cultures except those from the spleen. In the last the bacterium coli commune was found.

The staphylococci were found markedly virulent for mice, rabbits, and guinea-pigs.

Diagnosis.—Osteomyelitis of ulna; staphylococcæmia; acute endocarditis of aortic valve, with perforation into right auricle; acute endocarditis of right auricle. Point of primary invasion not demonstrable.

A Generalization on Aortic Regurgitation.—H. W. Syers does not believe that the majority of cases of aortic regurgitation are referable to rheumatism, but refers many cases to syphilis. He ascribes the sudden death, so often occurring in this form of valvular disease, to mural changes of the heart. It is perfectly obvious, he says, that the general imperfect filling of the arteries must be shared in by the coronary vessels, and hence it follows that the heart muscle itself must be more or less imperfectly nourished. Syers protests against the indiscriminate use of such remedies as digitalis and its congeners, simply because there is a murmur. So long as the discovery of murmurs is the end, aim, and object of heart examination, so long, I fear, will unnecessary and injurious treatment and meddling interference lead to the results which are only too often observed at the present time. Digitalis and other drugs of the class are nothing more nor less than most potent workers of evil in compensated heart lesion of all kinds, and in none more so than in aortic regurgitation. The already forcible contraction of the ventricle is rendered still more powerful, the strain on the arteries is increased, and the frequent contemporary presence of atheroma of these vessels may lead to the production of fatal cerebral hemorrhage. By the increased driving power of the ventricle, too, previously firmly adherent granulations may be swept away from the aortic cusps, and cerebral or peripheral embolism may be the result. Further, attacks of palpitation may be either excited or aggravated, and dyspeptic trouble, previously slight or absent, may be excited. And there is the further great danger of the heart being brought to a sudden and permanent arrest of action. Reliance should be placed on proper hygiene, in its broadest sense. Later, when compensation fails and the mitral value has yielded, the above-named remedies may find their proper application.—*Treatment.*

Therapeutic Value of Heat and Cold Applied to the Spinal Column.—W. F. Glenn offers the following summary: (1) Nothing should ever be put into the stomach except such substances as form a component structure of the body; (2) if this rule were rigidly adhered to, there should be no digestive disturbances, and we should always have a normal blood; (3) since the blood is the life, when the blood has its structural element normal and every cell is receiving its proper supply—no more, no less—disease cannot exist; (4) since we know that the amount of blood in any part is controlled by the action of the vasomoter centers of the spinal cord, and the sympathetic ganglia in close proximity to the cord, when these centers are performing their functions properly, the blood circulation must be normal, and no disease can exist; (5) when there exists any disease causing an increase of blood in the capillaries of an organ, the application of heat over the vasometer centers presiding over that organ causes almost at once a normal flow of blood in them, and, consequently, a normal circulation in the organ affected; (6) when there exists any disease which lessens the normal amount of blood in any organ, then the application of ice over the vasomotor centers presiding over that organ will cause a normal amount of blood to flow to that organ, resulting at once in a normal circulation, and a consequent subsidence of the disease.—*Nashville Journal of Medicine and Surgery.*

Acute Leucocythæmia.—Charles H. Melland says that the etiology and pathology of this disease are both obscure. That the affection is of an infective character is probable. The bone marrow is to be considered as the primary seat of the disease, the change in it being the initial and fundamental lesion preceding, or at least coincident with, the hyperplasia of the lymph glands, or in some cases occurring without any changes in the lymph glands, but in no case merely secondary to these latter changes. The disease occurs most commonly in young adults. The symptoms are weakness, dizziness, and palpitation, combined with those of acute febrile disorder, as headache and pain in the limbs. Fever is usually an early symptom. Hemorrhages from the mucous surfaces are common. The lymphatic glands are usually swollen. The spleen slightly enlarged. The diagnosis must, of course, rest on the blood examination. The red corpuscles are seriously diminished, and show marked evidences of degeneration. The increase in leucocytes is at times very great, but, as a rule, the numbers recorded are lower than in the chronic forms. The increase is solely in the lymphocytes. The prognosis is absolutely unfavorable, and treatment is confined to the symptoms.—*The Medical Chronicle.*

Venesection in Acute Nephritis.—R. W. Marsden reports two cases of acute nephritis, in which blood-letting was of value in restoring the circulation after cardiac failure. As to its effect upon uræmia, it is only conceivable that venesection would be of use in those cases in which, from whatever cause, the heart is no longer fulfiling its function properly, and there is a consequent increasing pressure in the venous system, so that in the treatment of uræmia one is again driven to the conclusion that the value of venesection is chiefly from the mechanical relief obtained. Springer suggests that better results might be obtained in the treatment of nephritis by venesection, if combined with the injection of fluid, but the author thinks that theoretical considerations are as little in its favor as in that of venesection alone. The latter alone, or in combination, is not to be adopted as a routine treatment for nephritis. But it is indicated when dilatation of the right heart follows overstrain and failure of the left ventricle, while the method of administration of fluids must depend on the needs of each case.—*The Medical Chronicle.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., EDITOR.

THOMAS L. STEDMAN, A.M. M.D., ASSOCIATE EDITOR.

WM. WOOD & CO., 51 Fifth Avenue.

New York, January 17, 1903.

THE ISTHMIAN CANAL COMMISSION.

ONE of the chief difficulties with which the constructors of a canal dividing the continents of North and South America will have to contend will be the unhealthy conditions prevailing in the regions through which the waterway must pass. Dire experience has already taught the lesson that the Panama route is extremely deadly to man, and especially to members of the white race. The mortality which attended the partial making of the ill-fated French projected canal was appalling, and was undoubtedly a factor in the final wrecking of that scheme. There is probably no part of the world where malaria of a malignant type is more rife than in the country surrounding the course of the contemplated Panama canal. Indeed, the entire district, including the alternative Nicaraguan route, is a hotbed of some of the most fatal diseases incidental to an almost untouched tropical land.

Taking into consideration then the unhealthiness of the environment and of the climate, it is in a high degree essential that the Government of the United States should use every means in its power to combat these conditions, and to render the work of constructing the canal as little harmful to human life as is possible. Effective sanitation must be the keynote of the efforts to attain this end. But in order that a good sanitary system might be evolved and properly carried out during the making of the American interoceanic waterway it will be necessary that a sanitary expert shall have an authoritative voice in the deliberations of the Isthmian Commission.

At the recent meeting of the American Association for the Advancement of Science, Prof. William H. Welch of Baltimore presented the following resolutions drawn up by himself:

"*Inasmuch* as the construction of the isthmian canal is through a region in which without energetic sanitary control there is sure to be enormous loss of human life from preventable diseases, particularly from pernicious malaria and yellow fever, as well as great waste of energy and of money from disabilities caused by such diseases, and

"*Inasmuch* as the measures for the restraint of these diseases, which have already achieved even their partial extermination in Cuba under American administration, require expert knowledge, based upon practical familiarity with tropical diseases, experience in the application of these measures, and large authority in their administration,

"*Resolved*, That the American Association for the Advancement of Science begs most respectfully and earnestly to call the attention of the President of the United States the importance of appointing as a member of the Isthmian Canal Commission a medical man possessed of the qualifications indicated. The association is convinced that the mere employment of such a sanitary expert by the commission will not be likely to secure the desired results.

"*Resolved*, That the permanent secretary of the association transmit a copy of these resolutions to the President of the United States."

The above resolutions no doubt embody the views of medical men throughout the country. A sanitary expert, to do the most good, is needed as a member of the commission itself, and it is to be hoped that the President will appreciate the force of this contention.

From a purely scientific standpoint, the field offered for research work, and for testing on a large scale the value of the discoveries relating to the conveyance and propagation of malaria and yellow fever by means of mosquitos is magnificent. A result of the digging of the isthmian canal may be that Americans will duplicate, or even surpass, the brilliant record made in Cuba. However, to bring such an event to pass, a man of high scientific attainments must be given a place on the commission, so that he will have the opportunity of impressing his colleagues with the supreme importance of the situation regarded from the outlook of medicine and science.

THE CHANGE IN THE ADMINISTRATION OF THE STATE HOSPITALS FOR THE INSANE.

IN its issue of February 1, 1902, the MEDICAL RECORD adversely commented upon Governor Odell's proposition to centralize the management and patronage of the eleven New York State insane hospitals, and to invest their control in a State commission in lunacy at Albany. It was then urged that the Charities Aid Association was an independent body, composed of persons of good standing and of unimpeachable integrity, and who had always labored earnestly and energetically in the interests of the insane.

The same editorial contained this paragraph: "The grounds upon which well-founded objections may be advanced against the proposed scheme of Governor Odell are that the State hospitals will be brought within the domain of politics. The boards of managers who have up to the present time supervised the institutions of the insane have been, at any rate, outside of politics. They have received no pay, and have performed their duties faithfully and well in the cause of charity alone. Perhaps their management has not been at all times distinguished by close economy, but some extravagance, when it directly benefits the patients and those attached to the institutions, is preferable to cheese-paring methods of conducting such establishments on political lines."

Despite strong opposition, the Governor was firm in carrying out his measures of reform, and after nearly a year's trial of the new system it would appear that the strictures passed upon the suggested

alterations have been amply justified by their ineffective results.

The Charities Aid Association has just published its tenth annual report to the State Commission in Lunacy, and gives over a large portion of its space to a critical review of the working of the legislation enacted last year on the recommendation of Governor Odell. With regard to the changes in the management of the State hospitals, the association thinks that the transference of superintendents and assistant physicians from one hospital to another, the abolition of the office of any of the resident officers and employees, and the transference of power of the superintendent to another officer, appointed by the commission, and endowed with special powers, has not been attended with corresponding benefits to the patients or any of those connected with the hospitals.

The report respecting these points says in part: "The subordination of the superintendent through the absolute control of a central body like the commission, and the power of this body to regulate the conduct of his hospital in every particular, to delegate his duties to another officer, to transfer him to another hospital, or even to remove him from the service, are disastrous to the success of the best hospital administration."

The steward is now appointed by the commission, and although virtually subordinate to the superintendent, is really more secure in his position than is the superintendent. This is necessarily prejudicial to the authority of the superintendent. The report goes on to say: "Many factors of the present system are, in the nature of things, discouraging and humiliating to the superintendents and other medical men in the hospitals, and young men of ability are deterred from entering the State hospital service, while many of the best physicians, it is to be feared, will abandon the service. The change in the personnel of the service will be gradual, but it is to be feared that it will be disastrous to the success of the State hospital system."

The association in its report recommends that the Lunacy Commission's appeals for a larger appropriation, as the amount provided last year was not sufficient to provide the patients with all that was needed.

The report concludes by recommending that small reception hospitals be established in large cities for examination of the alleged insane and for treatment of incipient and acute cases. The recommendation is also made that the consumptive insane be segregated, and that summer camps be established in the grounds of suitably located institutions, where hopeful cases may be cared for during the summer.

There is no doubt that the Charities Aid Association deserve well of the community for calling attention to the defects in the system of management of State insane hospitals inaugurated by Governor Odell. The MEDICAL RECORD has always held that politics should be wholly divorced from the management of charitable institutions, and especially of hospitals. Such establishments should be conducted solely in the interests of the afflicted, and should never be used in any way as a means of political leverage.

WOMEN AS ARMY NURSES.

THE belief has for some time been gaining ground that, in many respects, women are better fitted for the work of nursing wounded and sick soldiers than are men. The female nurse corps of the British Army has been fairly well tested, and, on the whole, has fulfilled expectations. Women trained nurses were first employed in the United States Army in May, 1898, and throughout the progress of the Spanish War, until at the end of the campaign there were nearly 1,200 in the service.

In the *Journal of the Association of Military Surgeons of the United States* for November, Dr. Anita Newcomb McGee contributes an article treating of the "Nurse Corps of the Army." Doctor McGee has always taken much interest in the question, and in 1899 wrote a notable article on the subject. According to this writer, in the period between 1898 and the present time the trained army nurses have served in Porto Rico, Hawaiian Islands, China, Japan, and Cuba, but in none of these places is there any need for them now.

The army nurse corps, as it exists to-day, is found at six large hospitals in the Philippine Islands—including about thirty nurses at the First Reserve in Manila—on the transport vessels, at the Presidio of San Francisco, at the tuberculosis hospital at Fort Bayard, New Mexico, and, from time to time, at any post where they are temporarily needed. The total number is 167, of whom 123 are in active service, and forty-four classed as reserves.

In December, 1900, the department placed in the Army Reorganization Bill, which came into effect that winter, a provision that the Medical Department should consist of certain officers, the hospital corps, and the nurse corps, thus placing the trained women nurses on the same footing with the hospital corps, as an integral and permanent part of the army—and consequently abolishing the contract system formerly in use. The pay and allowances are the same as were authorized early in 1899, but a "superintendent" has been appointed to the head of the corps.

The most important administrative work of the new superintendent has been an inspection tour of most of the army hospitals in the United States and Philippine Islands, at which nurses are stationed. Several valuable recommendations have been made as a result of this trip.

The writer is of the opinion that the trained nurses in the army might be used to a larger extent than at present as practical teachers of the enlisted men in the wards of certain large or base hospitals, just as in civil hospital wards the head nurses teach the juniors and prepare them, in their turn, to take increasing responsibilities, and to perform their duties more skilfully. This is the method of the English system, in which the "sisters," as they are called, act only as head nurses, and at the large hospitals, where they are stationed, they have the men under their instruction and orders. Their official grade is equal to that of second lieutenant.

Dr. McGee, as the outcome of her experience, makes the following suggestions: Graduate nurses who have had the benefit of a systematic three-year graded course in a large civil hospital could immediately, on their army appointment, be given a special post-graduate military course at a large

hospital—either at the one proposed to be located in Washington or in San Francisco—and at the same time could teach practical nursing in the wards to the hospital corps recruits. Since it is not possible to obtain any considerable number of male trained nurses, such use of carefully picked trained women nurses of the highest type is by far the best way in which the recruits can receive a training. As they enlist only for three years, and as part of their time is consumed in learning military duties from surgeons and stewards, their training should be continued at the large or base hospitals, so that they may go into the field or to smaller posts well prepared for their work. The permanent teaching force of the nurse corps, including perhaps one hundred nurses, should be of the highest possible standard, and should virtually hold their positions for life, as they do in England. They should be regularly stationed at certain specified hospitals, but whenever an officer at a smaller hospital needs them for an epidemic or a critical case, he should—as he now can and does—telegraph for two or more nurses to be sent from the nearest large hospital.

In addition to this permanent force, definite provision should be made for war reserves. The Army and National Guard will supply corps men for the arduous field service, but they cannot maintain a large enough corps to fill the needs of war emergency, with its large army and large percentage of sick, and neither can they turn recruits into competent nurses in a few weeks.

Therefore, the civil profession of nursing must necessarily be called upon, and definite provision for this should be made in advance, so that our Government may never be dependent on haphazard aid.

With reference to the nurse corps of the United States Army, and the need of an eligible institution in which to train persons for this service, the report of the Surgeon-General of the Army for 1902 reads thus, "The desirability of a place in some army hospital, in or near Washington, where nurses could serve a probationary period, is fully realized. The advantages of such an arrangement would be manifold. The superintendent would have an opportunity to observe personally each candidate before making recommendations for her permanent appointment, the examinations required by law could be made more thorough, and the risk of assigning unqualified or undesirable nurses to distant hospitals, involving a long and expensive journey, would be minimized.

Women nurses are particularly well qualified for a large part of the ordinary army nursing. In time of peace—with the possible exception of venereal diseases—they are better fitted, from most standpoints, to tend to those suffering from any malady, than men. In time of war the female nurse's place is in the base hospitals. This fact was clearly brought out in the recent South-African campaign, where, in the general hospitals, of about 500 beds, there were employed from twenty-eight to thirty women nurses, with most satisfactory results. Of course, however, to fill properly the position of army nurse, a thorough, practical training is necessary, and the opinion of a large number of army medical officers is to the effect that. be the probationer male or female, the teaching of the duties should be entrusted to trained nurses and not to medical men. It is declared that women nurses are effective teachers, and that men learn readily from them.

All belonging to the medical corps of the United States Army are agreed as to the need of an effective army nursing system, and, perhaps, the majority of them think that, wherever feasible, men nurses should be replaced by women.

THE TREATMENT OF THE SMOKE NUISANCE.

Since the coal strike in the anthracite regions began, and developed into the proportions it eventually assumed, dwellers in American cities, and especially in New York, have had a foretaste of what would happen if they were dependent upon bituminous coal for heating and lighting purposes. Not only this, but the population of large towns in this country have recognized that they must seriously consider such an eventuality, and be prepared with measures which will obviate the danger to health and the inconveniences that must assuredly follow the consumption of soft coal on a large scale.

In Great Britain the smoke nuisance has long been one of the most prominent questions confronting inhabitants of cities, and the difficulties in the way of abolishing, or even of lessening, the volumes of smoke which hang like a pall over London and Manchester and other large centers of population may be accurately gauged when the fact is taken into account that little or nothing has yet been done to remedy the evil.

At the meeting of the British Sanitary Congress at Manchester, held September 9 last, Mr. W. N. Shaw, Sc.D., F.R.S., read a paper on the treatment of smoke which was published in the *Journal* of the Sanitary Institute. Mr. Shaw proffers the suggestion that it might be well not to attempt to prevent smoke by penal legislation, but to encourage the interception of smoke and the removal of the sooty particles before the air containing them is allowed to escape. He does not put forward this plan as the best mode of dealing with the question, but merely wants to consider whether it is, *prima facie*, practicable enough to justify including inquiries with regard to it in the demands that sanitation may reasonably make upon science.

The idea which Mr. Shaw has in mind is that proposed by Mr. Peter Spence or Manchester many years ago, namely, the erection of municipal chimneys, whereby a single smokestack should be provided for a considerable number of independent fires. "The existence of this practice," says the writer, "makes me regard the separate opening on each chimney of the domestic house into free air as not absolutely required by any physical laws governing the removal of smoke. The factory builder is not always successful in using his chimney for preventing smoke, but he is successful in leading the foul air of many flues into one channel, which might afford an opportunity for depriving the smoke of its soot."

Moreover, arrangements for propelling air mechanically are becoming every day more extended. Some of them, as employed in various systems of ventilation, are quite as elaborate as any that would be required to deal with the smoke of an ordinary house, or block of houses. Laboratories and other build-

ings of a similar character are provided with special means, mechanical or thermo-mechanical, for removing noxious fumes. There is no sufficient distinction to be drawn between coal smoke and other forms of refuse that foul the air to make it necessary to use one system for the former and a different one for the others. It thus seems almost certain that if the domestic architect had sufficient encouragement to make the attempt, he would not find the plan of dealing with household smoke by the method of the factory chimney, or by mechanical propulsion, beyond the range of practical physics.

The plan suggested is, in short, to concentrate the output of smoke as much as possible, and then to drive it away, by means of electrical fans, to certain points for treatment on a mode somewhat similar to the treatment of sewage.

As to treatment, Mr. Shaw, after saying that he does not suppose it to be possible to establish a few main drains for smoky air corresponding to the main sewage drains, and to use one or two cleansing stations for purifying the air from smoke, goes on to state his opinion that it might be possible to achieve a similar result by a large number of systems on a correspondingly small scale, and the systems might be some of them municipal and some private. Electricity, he also thinks, might be used as a means of purifying smoke, following the principle that sooty particles coagulate under mechanical action, and in a line with experiments made some years ago by Sir Oliver Lodge on the deposition of smoke in a closed chamber by the action of electricity.

The paper read by the British scientist refers entirely to conditions in some of the large cities of Great Britain, and would not apply to the smoke question in any American towns. Nevertheless, it is instructive in many respects. It shows how difficult it must be to deal successfully with the smoke nuisance when a man of Mr. Shaw's experience and repute can point to no definite remedy, but can only suggest measures that will seem, to the majority of persons, visionary, and would be, besides, of a cost almost prohibitive.

Geographical Distribution of Stone and Calculous Disorders.

Mr. Reginald Harrison, F.R.C.S., read a paper with this title at the Congress of Medicine, held in the autumn of last year in Egypt.

The writer drew attention to the well-known fact, that the distribution of stone throughout the world is very varied and irregular. In Great Britain with her colonies and dependencies, there is abundant evidence of this. In some districts of England and the British Isles, as, for instance, in the Eastern counties, stone is common, whilst in other parts, amongst which may be included the whole of Ireland, it is remarkably rare. In British India these contrasts are still more remarkable. In the United States and Canada similar differences exist, but not to the same degree.

"In analyzing the evidence," says Mr. Harrison, "deducible from the fact that such varieties are to be found in the distribution of calculous disorders, stress has been laid upon certain differences in the conditions under which the inhabitants of respective countries live. These have reference mainly to the food and drink supply, to climate and to States incidental to the latter—for instance, a local liability to certain parasitical affections, or to physical conditions of the urinary apparatus favorable to these concretions."

Dr. Patrick Manson has pointed out that there are two kinds of stone whose etiology are positively known; those found on foreign bodies, and on the ova or débris of bilharzia. Mr. Freyer has also shown that about one-third of the cases of stone he had operated upon in England were complicated with enlargement of the prostate. These conclusions, Mr. Harrison thinks, taken in conjunction with the statement that there was ten years' difference in the expectancy of life in favor of the inhabitants of England as compared with India, indicated that structural obstruction, as a consequence of age or otherwise, must be regarded as a factor in the production of urinary calculi.

In short, Mr. Harrison is inclined to think that geographical considerations carry more weight in searching for the cause of stone than is reasonable, and that there are other factors in the forming of such concretions which require investigation. At the same time local conditions of soil, water, and climate have their influence on the production of urinary calculi. The writer regards stone as a preventable disease, and concludes by saying that when it occurs in endemic proportions it is deserving of further notice. It is a symptom and not a disease.

Ethyl Chloride as an Anæsthetic.

The *Lancet* at the end of every year has for some time been accustomed to pass in review the medical and surgical events of the preceding twelve months. The close of the past year was no exception to this rule, and in its issue of December 27 is given a retrospective survey of the notable happenings in the medical world during 1902. The writer of the *Lancet's* annus medicus, recognizing the great importance of anæsthesia, has devoted a large portion of space to a consideration of new methods of anæsthesia, and especially singles out ethyl chlorid for critical discussion.

He writes thus concerning this compound: "Ethyl chlorid, although called a 'new anæsthetic,' was really discovered by Flourens fifty years ago. H. Girard has given the result of a most exhaustive research upon chlorid of ethyl. Girard's conclusions show that the physiological action of ethyl chlorid resembles closely that of the other members of the ethyl series. In that it contains chlorine it is more of a protoplasm poison than the oxide. Its extreme volatility, however, invests it with advantages and drawbacks entirely its own. Thus it has to be given undiluted by air. The rapidity of the action of the concentrated vapor in most persons minimizes the pre-paralytic stage of excitement, although Broadtbeck, Lotheissen, Gires, and others have recorded, although rarely marked, excitement with noisy talking even when the patient was wholly unconscious. These phenomena were most marked in alcoholic and neuropathic patients. As the mucous membrane of the upper air passages becomes rapidly anæsthetic it is claimed that reflex cardiac syncope does not occur as a result of ethyl chlorid. However, Girard points out that reflex inhibition of respiration may supervene, although it rapidly disappears, and we are compelled, therefore, to regard his conclusion as to cardiac inhibition being always absent as at present open to further examination. The cumulative action of ethyl chlorid prevents its employment for prolonged operations, at least for such as do not allow the alternate narcotizing and recovery of the patient. The rapidity of the recovery renders it extremely difficult to prevent complete return to consciousness before the removal of the

inhibition. As far as our knowledge goes at present this anæsthetic appears at its best in brief operations. It is well spoken of by Girard for use in minor surgery and dentistry. Its rapid action, the speedy recovery of consciousness, and the absence of after-effects as well as its portability are, he thinks, its best qualities."

Others have used ethyl chlorid in ophthalmic practice with much satisfaction and no unpleasant results, but, taking into consideration its volatility, and the consequent difficulty of keeping a patient unconscious for any length of time, it would appear that this anæsthetic is better adapted for minor surgery and dentistry than for operations on a large scale.

In the course of the article on anæsthetics the writer says, "the most important event of the year was undoubtedly the step taken by the Royal College of Physicians and Surgeons of England in compelling medical students to obtain a practical knowledge of anæsthetics and their administration before admission to the final examination."

It is in a high degree useful, and in many instances of the most vital importance, that medical men should possess a knowledge of anæsthetics and their mode of administration. This knowledge is of particular value to country practitioners, who often have to give an anæsthetic unaided, and whose inability to do so correctly has been in the past the cause of many fatalities.

The Doctor in Literature.

Now and then some busy physician takes to writing a book on some other subject than that of medicine and gives the purely human side of the song within him. If more of this work were done, pathetic, sentimental, and poetical literature would be proportionately enriched. The latest notable effort along such lines is that of Dr. W. S. Gordon of Richmond, Va., who gives in "Recollections of the Old Quarter,"* one of the best phonetic studies of the negro dialect that has yet appeared. True to his instinct, he has brought a trained habit of thought into its task which proves him a literary artist of high class. To such as are acquainted with the ways, habits, and sentimental character of the Southern negro, the "old Dinahs" and "Uncle "Uncle Abe's" are alive again with their quaint descriptions, weird supersitions and musical intonations. Aside from this there is woven in the reminiscent stories of the speakers the high literary elements of incidental scene and place which make the situation real, natural, and telling. When the author speaks for himself he is equally felicitous, with a smoothness and grace of style that proves eminently his fitness for his task. Would that more leisure hours of talented medical men could be given to similar efforts. How much indeed of the sentiment and pathos of a doctor's life might thus be presented to enrich our general literature and broaden the plane of a common human sympathy.

The Treatment of Tetanus.

In the United States within the past year there has been one serious epidemic of lockjaw and another of lesser extent. These unfortunate occurrences have drawn the attention of the medical profession to the disease, and the modes of prevention and treatment have been discussed at length. The old routine treatment of isolation and silence, together with the administration of chloral in large doses, has almost died out, and the injection of antitetanic serum and of carbolic acid have taken its place.

Dr. Vallas of Lyons, at the recent meeting of the Congress of Surgery, read a long report on the treatment of tetanus, a part of which was given in the Paris letter of the Medical Record of January 3. The writer pointed out a fact which does not appear to be thoroughly recognized, namely that the antitetanic serum is really not anti-tetanic but antitoxic, and that, consequently, the wound requires most energetic treatment. As a preventive, however, it is claimed that the serum is efficacious. Dr. Vallas states that whenever a wound is of a suspicious nature an injection of 10 c.c. should be made the first day, the same amount the third and tenth day. In case the wound is not healed, the injection should be repeated every fifteen days.

Bacelli's treatment of lockjaw by injection of carbolic acid has been attended with great success in Italy and elsewhere. The method consists in the injection of a 2 to 3-per-cent. solution of carbolic acid. About 30 to 40 cgs. of carbolic acid should be injected daily. Injections of hydrogen-peroxid have been tried successfully on horses, as have intravenous injections of an iodide solution. It would seem then that in order to prevent an attack of tetanus, the serum should be used, while for purposes of treatment carbolic acid is a most valuable adjunct. There are those, however, who hold that carbolic acid is almost a specific in lockjaw, and the wonderful results reported from Italy from the administration of this antiseptic would almost make one believe that such is the case. On the other hand, it is asserted that tetanus is less deadly in Italy than in many other lands. Further investigation is needed before a strict line of treatment can be laid down, but in the meantime the weight of evidence shows that carbolic acid is a factor of much importance in the treatment of lockjaw.

Smallpox and Vaccination.

In the *Lancet* of December 27 is a review of the epidemic of smallpox which prevailed in London during the greater part of the past year, and the efficacy of preventive measures, and especially of vaccination. Many of the remarks made by the writer in the British journal may be applied with equal force to the situation as regards the attitude of the majority of the population toward smallpox and vaccination in this country. Those persons who are not actively opposed to vaccination are for the most part in no fear of smallpox, and consider vaccination as a somewhat unnecessary nuisance. This indifferent frame of mind has been brought about by the fact that no deadly epidemic of the disease has attacked the United States for a considerable time. The type of the malady seems to have become mild. Therefore, it is argued if smallpox does not often kill, what is the use of putting ourselves to the bother and discomfort which vaccination entails. That such an argument is fallacious, and that those who hold the belief are living in a fool's paradise is patent to men who are well versed in the matter. However, this phase of the subject was amply discussed in the Medical Record a short time ago.

The *Lancet*, referring to small pox in its last issue of the year 1902, says: "The recent prevalence of smallpox has taught certain lessons. In the first place we have seen, contrary to the teaching of the anti-vaccinationists, that smallpox is in no sense dead. It is true that in the recent outbreak we have not seen any serious approach to a malignant type of the disease, but we have experienced enough to know that smallpox is still at our gates, and that if we wish

* "Recollections of the Old Quarter," by Wm. S. Gordon, M.D., Lynchburg, Va.

to keep it at bay we must not relax preventive measures. In connection with the subject of revaccination, the fact has been inconveniently brought home to us that if the majority of individuals postpone the operation until smallpox is actually in our midst, an almost breaking strain is put upon our administrative machinery, both in respect to the preparation of a sufficiently potent lymph and to the actual performance of a revaccination. Panic vaccination is unsafe for the individual and unfortunate for the cause of vaccination. With respect to other preventive measures, the enormous importance as regards limitation of the spread of the disease by its early recognition has been again accentuated. Inasmuch as in the absence of smallpox few medical men can become thoroughly familiar with its manifestations, there is the more need that there shall be a systematic arrangement by means of which those who have had actual experience with smallpox shall be available for the assistance of those less experienced, and such a provision should be always in readiness."

The need of being able to make an early diagnosis is so evident as to require but little emphasizing. Smallpox is spread by the inability of a medical man to make a quick and correct diagnosis. In view of this fact, it would be to the benefit of all concerned if physicians were to use every means to render themselves conversant with the various idiosyncrasies of the disease.

Typhoid Fever Due to Oysters.

We have only recently had occasion to refer to a conspicuous illustration of the part played by the consumption of oysters in the transmission of typhoid fever. The case was that of Winchester, Eng., but a no less demonstrative example nearer home has just been recorded by Dr. Philip Marvel in a paper read before the Philadelphia County Medical Society (Proceedings of the Philadelphia County Medical Society, December, 1902, p. 339). There occurred in Atlantic City during the latter part of the summer of 1902 an unusually large number of cases of typhoid fever which could not be traced to the ordinary sources of infection. Persistent investigation, however, disclosed the fact that some of the oysters intended for local consumption were being freshened or fattened in a canal but a short distance from a point where sewage was being poured into the waterway; and it was also known that there had previously been cases of typhoid fever in the city whose excreta had found their way into the sewage. That the outbreak of the epidemic was actually due to the consumption of contaminated oysters was conclusively demonstrated by the fact that new cases of the disease ceased to develop after the sale of oysters and clams subjected to the freshening or fattening process was prohibited under legal penalty.

"The Medical Library and Historical Journal" is the title of a new journal, the first number of which is announced for publication this month. It will be devoted to the interests of medical libraries. Its original articles will treat of medical history and biography, practical medical library administration and economy, medical bibliography, the care of books, the history, construction, and use of medical libraries, etc. A feature of the journal will be the publication of a complete index medicus of every current medical book, both English and foreign. The journal is to be published quarterly, and is to be edited by Messrs. John S. Browne and Albert T. Huntington.

News of the Week.

The Medical Society of the State of New York.—The annual meeting of this society will be held in Albany on January 27, 28, and 29, under the presidency of Dr. Henry R. Hopkins of Buffalo.

A Research Fellowship in Medicine at the College of Physicians and Surgeons.—A new fellowship in medicine of the annual value of $1,200, and tenable two years, has been established at Columbia University. The fellowship is to be known as the Proudfit Fellowship, in honor of the late Alexander Moncrief Proudfit of the class of '92, who left a large bequest to the university. It is established distinctly for research work, and is to be offered to graduates of the College of Physicians and Surgeons to enable them to pursue advanced study and research in internal medicine either in this country or in Europe. Awards will be made once in four years.

Proposed Amendment to the Milk Law.—A bill will soon be introduced into the New York State Legislature amending the present law in such a way that the possession of each can of inferior milk will constitute a distinct violation of the law. This bill, which will be introduced on behalf of the State Department of Agriculture, results from the recent decision of the Court of Appeals in a Rochester milk inspection case. Under the decision the quality of milk delivered by a dairyman or dealer must be judged from an average sample of all his cans. This decision has all but nullified the milk inspection law, since a dealer might have several cans each of adulterated and pure milk, selling only from the former, but an average sample of all might be up to the standard.

Alumni Association of the College of Physician and Surgeons.—A reunion of the Alumni of the College of Physicians and Surgeons, under the auspices of the Alumni Association, will be held at Sherry's, Fifth Avenue and Forty-fourth Street, Monday, January 19, 1903, at 8.30 P.M. There will be a vaudeville entertainment with supper.

A New Hospital for Gastric and Intestinal Diseases.—Application was made last week to the Board of Charities at Albany by several men residing in this city for permission to incorporate for the establishment of the "McKinley Memorial Hospital for Diseases of the Digestive Organs." The Directors mentioned are: Dr. Mark I. Knapp, Dr. Ramón Guitéras, Dr. Reynold W. Wilcox, Dr. Carl Beck, and Mr. Edward Lauterbach.

An Institution for the Study, Prevention, and Treatment of Tuberculosis.—It is announced that Mr. Henry Phipps of New York will establish in Philadelphia an institute for the study, prevention, and treatment of tuberculosis. It is proposed to erect buildings in the center of the city, in the midst of the poor, at a cost of from $200,000 to $300,000. An endowment of $1,000,000 is to be provided, yielding an income of $40,000 annually, which is to be devoted to maintenance. The institute, which is to be named after its benefactor, is intended to be a center for the distributon of knowledge concerning tuberculosis, with the object of stamping out this disease. There will be an administration building containing a Finsen light department, a hydrotherapeutic department, with baths and electric appliances, and also pavilions with a capacity of 100 beds for the treatment of advanced cases of pulmonary tuberculosis. There will, further, be a dispensary for the treatment of walking cases. From this source assistance will be given poor tuberculous patients in their homes, and a general

supervision will be kept over them for the purpose of instructing them in methods of preventing the spread of the disease. They will be supplied with disinfectants, sputum cups, and paper napkins, and be taught their use. Their homes will be disinfected when necessary, and the clothing of the extremely poor will be disinfected and washed, and these will even be supplied with food of the proper kind when necessary. Lectures will be given and conferences held on the subject of tuberculosis, and steps have been taken looking to the holding of the International Congress of Tuberculosis at Philadelphia in 1905. An effort will be made through the institute to correlate the various forces of the country engaged in the crusade against tuberculosis, and make this movement more effective through united endeavor. It was intended to begin the work at once in a temporary building rented for the purpose, but an obstacle has been found in a Pennsylvania law which forbids the erection of hospitals in the built-up parts of any city in that State. Dr. L. F. Fick, who will be medical director of the institution, says that, unless the law mentioned is repealed, the idea of establishing the institution in Philadelphia will be abandoned, since one of the chief purposes of the institution is to keep it in close touch with the poorer classes, and this can be accomplished only by having it in the midst of their homes. It will not be erected in the suburbs of any city, but only in a crowded section. If the bill for the repeal of the law is defeated in the Legislature, the institution will be established in New York City.

Bequests to Philadelphia Hospitals.—By the will of the late Henry C. Cochran of Philadelphia the following bequests are made, to become effective on the death of his widow: To the Presbyterian Hospital $5,000, to endow a free bed in memory of his mother; to the Pennsylvania Hospital $10,000, one-half for the department for the insane; to the University Hospital $5,000; to the Philadelphia Polyclinic, the Gynecean Hospital, and the Medico-Chirurgical Hospital, each $1,000; to the Philadelphia Dispensary and the Northern Dispensary, each $500. By the distribution of the estate of the late Thomas Elkinton, Jefferson Hospital, the Orthopedic Hospital, the Polyclinic Hospital, and the Hospital of the University of Pennsylvania, each receives a legacy of $5,000.

Death Rate of Philadelphia.—According to the annual report of the Philadelphia Board of Health, the death rate of that city for the year 1902 was 17.67 per 1,000, as compared with 18.26 for 1901 and 17.17 for 1879. Among the principal causes for death during the year were as follows: Pneumonia, 2,976; pulmonary tuberculosis, 2,845; diseases of the heart, 1,681; Diphtheria, 435; smallpox, 231; scarlet fever, 143.

Protestant Episcopal Hospital of Philadelphia.—The Board of Managers has recommended the erection, at an early date, of a separate dispensary building, at a cost of $75,000. Preparations have been made for the erection of a ward for patients suffering from contagious diseases. During the fifty years of the existence of the hospital 65,000 patients have been treated at a cost of $2,500,000, and 714,000 patients have been treated in the dispensaries.

Pennsylvania State Medical Examinations.—As a result of the recent examinations, licenses to practise medicine in the State of Pennsylvania were granted to 64 of 77 applicants. It is said that the papers gave evidence of a marked improvement in the standing of those that passed the examinations successfully. At present all candidates are required to possess a preparatory education not below the standard of a high school, and they must have spent at least four years in a recognized school of medicine.

Typhoid Fever and Smallpox in Philadelphia.—For the week ending January 3 there were reported to the Philadelphia Board of Health 532 deaths—sixty-two more than for the week before, and forty-four more than for the corresponding week of the previous year. Of the whole number, 165 were due to diseases of the lungs; fifty-two deaths were attributed to disease of the heart. There were reported 144 cases of typhoid fever, with ten deaths; sixty-three cases of scarlet fever, without any death; fifty-two cases of diphtheria, with nine deaths, and fifteen cases of smallpox with one death. Nearly one-third of the cases of typhoid fever were reported from parts of the city supplied from the Queen Lane reservoir, and a suspicion exists that the water is obtained by direct pumpage from the river, though this is denied by the authorities. Active measures have been undertaken to prevent the spread of smallpox, and additional assistant medical inspectors have been appointed to see that all persons are properly vaccinated.

Professor Lorenz arrived in England last week, and has been repeating his American experience in the way of clinics and courtesies from his medical brethren in Liverpool and London.

Pathological Society of Philadelphia.—At a stated meeting, held January 8, Dr. J. Dutton Steele exhibited preparations showing the anatomy of the bile-ducts and gall-bladder. Dr. Jos. Sailer exhibited a series of heart lesions. Dr. D. J. McCarthy exhibited a brain from a case of Sydenham's chorea. The specimen came from a young man who had had choreiform movements in conjunction with pain, swelling, and redness in several joints. The brain presented several large cavities that developed in consequence of imperfections in the technique of preservation, and which were found to depend upon the bacillus mucosus capsulatus. No actual lesion was found in the cerebral structure. Dr. D. J. McCarthy presented a communication entitled "A Contribution to the Study of the Formation of the Hemolymph Glands from Adipose Tissue in the Human Beings." The observations were made on the bodies of two patients that had suffered from adiposis dolorosa. Dr. McCarthy presented a brief communication also on "The Pathology of Forage Poisoning." The observations had been made upon horses that suffered from weakness, delirium, and spasm, in consequence, probably, of the ingestion of contaminated food, and no constant lesion was found. In a number of instances, however, a proliferation of new cells was noted surrounding the capsules of the nerve cells in the intervertebral ganglia. Drs. Henry M. Fisher and Wm. T. Longcope exhibited the specimens from a case of acute ulcerative endocarditis of the pulmonary valves. The patient had previously suffered from attacks suggestive of rheumatism, and systolic and diastolic murmurs were heard over the heart during life. After death extensive verrucose and ulcerative endocarditis was discovered, involving the pulmonary valves, and apparently extending to the interventricular septum, through which a perforation had taken place, the opening, however, being occluded by a thrombus.

College of Physicians of Philadelphia.—At a stated meeting, held January 7, Drs. Wm. G. Spiller, John H. Musser, and Edward Martin reported a case of intradural spinal cyst with operation and recovery. The patient was a young woman, who presented pain in the distributon of the third and

fourth lumbar nerve-roots, first on the left and then on the right side, increased knee-jerks on both sides followed by loss later on one side, and beginning paralysis in the lower extremities. Despite the utmost care at the operation, the cyst, which had exceedingly thin walls, ruptured before its contents could be received into an appropriate vessel, so that the exact nature of the formation could not be determined. The possibility of its being an echinococcus cyst or a cysticercus cyst was suggested. The improvement following operation was noteworthy—pain, exaggeration of reflexes, and paresis disappearing. Drs. Joseph Sailer and Robert D. Rhein presented a communication entitled "A Case of Eventratio Diaphragmatica; with an *X*-Ray Picture of the Patient by Dr. Pfahler." The patient was a chronic epileptic, who was seized with typhoid fever, and in whom the percussion-note was tympanitic over the lower third of the left chest, while the heart was displaced to the right. The case was suspected to be one of diaphragmatic hernia, but, on post-mortem examination the left half of the diaphragm was found to occupy an unusually high position, its concavity being occupied by the stomach and intestines, while the left lung was hypoplastic, and the heart was displaced to the right. Dr. Horatio C. Wood was re-elected President, Dr. Arthur V. Meigs, Vice-President; Dr. Thos. R. Neilson, Secretary, and Dr. Richard H. Harte, Treasurer. Dr. Wm. C. Gorgas, Major and Surgeon, U. S. A., and Dr. Charles Finlay of Havana were elected Associate Fellows, and it was announced that a like distinction was in contemplation for the late Major Walter Reed, U. S. A., prior to his untimely death. Dr. S. Weir Mitchell announced that he had received from Mr. Andrew Carnegie a gift of $50,000 for the purpose of enlarging the library building on condition that the college provide an equal sum.

American Association for the Study of Inebriety.—The thirty-second annual meeting of the American Association for the Study of Inebriety was recently held in Boston at the Washingtonian Home, under the presidency of Dr. L. D. Mason. Resolutions were adopted condemning the indiscriminate use of medicine for the alcohol and opium habits, and suggesting that institutions be licensed and inspected which are to care for inebriates, or victims of narcomania. Dr. L. D. Mason of Brooklyn read a paper on "Patent or Proprietary Medicines as the Cause of Either the Alcohol or Opium Habit, or Other Form of Drug Habituation, and Some Suggestions as to How the Evil May Be Remedied, and the Public Protected." It was urged that a general campaign of education be insisted upon, and that an increasingly careful study be made of the underlying causes which lead up to the conditions under consideration. Dr. H. D. Rodebraugh read a paper on the "Value of Surgery in Certain Cases of Inebriety." He urged the necessity of considering the physical side of the patient, and spoke of the good effects of simple surgical operations. Dr. Edward Cowles read a paper on "Legislation for the Control of Inebriety." He drew attention to the English law on the subject, and spoke of the somewhat different conditions existing in the United States, where a probation system, longer confinement, establishing industrial colonies, and similar ideas have influenced legislation. He urged that the probation system be made more useful, and that a better understanding be established between magistrates, probation officers, and hospital authorities. Dr. S. B. Elliott spoke on the subject of "Restraint and Moral Measures in the Treatment of Inebriety." Dr. Elliott suggested the desirability of separating incurable from curable patients, and he insisted upon the medical rather than the criminal aspect of the subject. Dr. Agnes Sparks read a paper on "Plans of Treatment for Women Inebriates." "The Hydropathic Treatment of Inebriety" was the subject of a paper by Dr. C. A. Shephard. Dr. Shephard insisted upon the very great value, for obvious reasons, of cleanliness for the preservation of general health. Dr. J. H. Kellogg spoke on "Diet in the Treatment of Inebriety." Dr. J. W. Mattison, in dealing with the subject of "Narcotic Abuses and the Public Weal," spoke strongly against the wide sale of nostrums containing narcotic drugs. He urged the adoption of restrictive laws such as are in force in Germany. Dr. T. D. Crothers read a paper on "Inebriety in Ancient Egypt and Chaldea," in which he showed the similarity between the situation regarding alcohol at that time and at the present day. The following officers were elected: *President*, Lewis D. Mason, Brooklyn; *Vice-President*, Charles H. Shephard, Brooklyn; *Corresponding Secretary* and *Treasurer*, T. D. Crothers, Hartford; *Recording Secretary*, J. J. Wagner, Greenwich.—*Boston Medical and Surgical Journal.*

The Death Rate from Malignant Disease in London—According to a despatch to *The Sun*, the statistics printed by the London County Council of the mortality from cancer in that city during 1902 shows that there was a slight decrease in the death rate, the percentage being .93 per 1,000, as compared with .95 in the previous year. The proportion, however, has been more than doubled within fifty years, the rate between 1851 and 1860 being .42. Even in the year 1891 it was only .78. Comparatively few deaths from cancer were reported before the year 1855.

A Medical Member of the Panama Canal Commission.—The American Association for the Advancement of Science, which met in annual session in Washington on the first of this month, voted to request President Roosevelt to appoint a physician as a member of the Isthmian Canal Commission.

Lemon-juice and Typhoid Fever.—The energetic Health Commissioner of Chicago proclaims his continued trust in the bacillicidal virtues of lemon-juice. In the latest bulletin at hand of the Department of Health he says: "Further laboratory study of the action of lemon-juice on the typhoid germs confirms the results previously announced. The investigation has been extended to its action on the colon bacillus—first cousin of the typhoid and the cause of diarrhœal and dysenteric diseases, which carry off many more victims every year than does typhoid fever at its worst. It is found that the juice from different specimens of fruit varies greatly in destructive power, and the proportion stated last week—one teaspoonful to half a glass of water—is none too much. The action of the acid is instantaneous." In the meanwhile the New York City Health officials, according to the daily papers, continue to scoff at the hasty conclusions of the Chicago people, and Buffalo, being geographically placed between the two contestants, has decided to arbitrate the difficulty. It is stated in a recent despatch that Health Commissioner Greene has directed the physicians of the bacteriological department to make investigations relative to the merits of lemon-juice as a destroyer of typhoid bacilli, being prompted to take this step by the conflicting reports received from New York and Chicago.

The Revived "Index Medicus."—A prospectus has been issued giving information concerning the new *Index Medicus*. This invaluable publication was established in 1879, under the editorship of Drs. John S. Billings and Robert Fletcher, and was discontinued in 1899. The present publication, which is

undertaken by the Carnegie Institution, will be known as *Index Medicus*, Second Series, and will be under the editorial charge of Dr. Robert Fletcher. The first number will appear in January, 1903. It will consist of the titles in full of books, pamphlets, theses, contributions to coöperative works, and original articles in journals, transactions of medical and scientific societies, and the like, arranged under subject-headings. It will be issued as early as possible after the first day of the month, time being allowed for the arrival of foreign journals, and will represent the literature of the preceding month. A table of contents will accompany each number, and on the completion of the volume an "Annual Index of Authors and Subjects" will be issued. The subject part of this annual index will be elaborately subdivided, the classification closely resembling that of the Index Catalogue of the Library of the Surgeon-General's Office. The annual index of the last volume of the first series occupied 156 pages in double and triple columns. The titles in certain languages, as Russian, Polish, Swedish, Danish, Finnish, Hungarian, Bohemian, Roumanian, and Japanese, will be translated into English. The editor, while indexing all really original matter, will not admit "reports of progress" or include all copies of an article which may appear in other journals. Translations will be admitted when in languages more familiar than the originals. The classification by subjects which will be adopted in the monthly numbers, will closely follow that which use made familiar to the readers of the first series, but with such additions and modifications as advances in medical knowledge may require.

The Health of New York State.—It is reported by the State Board of Health that the State's mortality during the three months ending December 31 was one-tenth of 1 per cent. less than last year. There has been less prevalence of most infectious diseases and of diseases affecting infancy and childhood, but the records show an increase in maladies of the respiratory, circulatory, and nervous systems. The total of deaths was less than the average of the last five years for the corresponding period.

Gift of a Laboratory to the Orange Memorial Hospital.—A fully equipped bacteriological and pathological laboratory has been presented to the Orange Memorial Hospital by Dr. William B. Graves of East Orange. It will be known as the Graves Laboratory. A large room has been set apart in the dispensary building, and it will be at the disposal of private physicians as well as the hospital. The new laboratory will save considerable delay, as at present it is necessary to send cultures and specimens either to New York or to Princeton.

Defective Ambulance Service in London.—In a recent issue of London *Truth* it is said that the inadequacy of the ambulance service in that city is clearly shown in the report presented by Sir William Collins to a committee of the London County Council. A record has been kept of ten of the large London hospitals of the mode in which casualties were brought in. Out of 994 injured persons arriving 642 came in cabs or carts, 302 in different kinds of ambulance, and 50 by other means of conveyance. "The fact is," the writer concludes, "that for the general public in London there is no ambulance service worth the name."

Koch Investigating the South-African Cattle Plague.—Dr. Robert Koch has gone to Beira to investigate the cattle plague of Rhodesia. This disease, it is said, is wholly different from any other known form of cattle plague, the first cases having been noted during the recent war.

The Microbe of Rabies has, it is claimed, been isolated by Professor Sormagin of the University of Pavia. No details are given in the dispatch announcing the discovery of the nature of the microorganism.

A Memorial to the Late Major Walter Reed.—At the annual meeting of the American Association for the Advancement of Science, a committee to secure a suitable memorial to the late Dr. Reed was appointed as follows: Dr. D. C. Gilman, Prof. Alexander Graham Bell, ex-Surgeon-General Sternberg, U. S. A.; Seth Low, J. G. Schurman, W. H. Welch, A. S. Hewitt, C. S. Minot, and S. E. Chaille.

A Lecture on Ankylostomiasis.—On Saturday evening, January 17, at 8.30 P.M., at the Medical Library Building, 1313 Bedford avenue, Brooklyn, Dr. Charles Wardell Stiles of Washington will deliver an address under the auspices of the Medical Club of Brooklyn on "Hookworm Disease (Uncinariasis)—A Newly Recognized Factor in American Anæmias."

Expert Anæsthetists for Bellevue and Allied Hospitals.—The Board of Trustees for Bellevue Hospital and the allied hospitals has appointed Dr. Myron P. Denton and George M. Creevey to Bellevue and Dr. Samuel J. Kopetzky to Harlem Hospital as expert anæsthetists. Their duties are to instruct the incoming members of the house staff to administer different anæsthetics, and to exercise general supervision of the use of anæsthetics. As soon as suitable anæsthetists can be obtained appointments will be made to Gouverneur and Fordham hospitals.

Reduced Rates for the Annual Meeting of the American Medical Association.—The General Agent of the Southern Railway Company announces that the Southern Railway has authorized the rate of one fare for the round-trip to New Orleans from Washington and all prominent points on its system throughout the entire South. Dates of sale May 1, 2, 3, and 4, good for continuous passage in each direction, with final limit of ten days from date of sale. Tickets can be extended for longer period, however, provided they are deposited in person, by the original purchaser, with the Special Agent at New Orleans not later than May 12, 1903, and a fee of fifty cents is paid at time of deposit, when the final limit will be extended to a date not later than May 30, 1903.

The Plague in San Francisco.—Dr. Walter Wyman, Surgeon-General of the Public Health and Marine Hospital Service, sends the following correction of a newspaper report concerning an alleged statement of Dr. Glennan: "I note that in the number of the MEDICAL RECORD for December 27, 1902, there appears under the caption 'Fresh Denials from San Francisco.' an item based upon an alleged interview in the San Francisco *Call* with Surgeon A. H. Glennan of this service, now at San Francisco, California, in which Surgeon Glennan is made to say that the plague does not now, and never has prevailed in San Francisco, and that the bacillus of the disease which existed there was that of chicken cholera. I would invite your attention to the fact that, under date of December 14, 1902, Surgeon Glennan telegraphed the Bureau that the statement attributed to him by the *Call* was false. An authoritative denial was published in the Sacramento (California) *Bee* of December 16, 1902." A statement of similar import was attributed to Dr. Wyman himself by the agents of an alleged "news" service in Washington, on the occasion of his return from San Francisco two weeks ago. Dr. Wyman very promptly denied the truth of the report, but few of the papers that had published the manufactured statement thought it necessary to give place to his denial. In the meanwhile some of the Australian ports have

quarantined against San Francisco, on the ground that the reports of the State Health Department cannot be depended upon. Dr. Eagan, secretary of the British Columbia Board of Health, who went to San Francisco to investigate the reports regarding the bubonic plague, has made a report to the British Columbia Government in which he says that rats that have been found dead in San Francisco have showed plague bacilli when examined. He recommends that strict quarantine be maintained against vessels arriving from that city. In response to the urgent requests from numerous State health officers, Surgeon-General Wyman has called a conference of the Public Health and Marine Hospital Service with the health representatives of nineteen States, to meet in Washington, January 19. This is the first advantage that has been taken of the law of 1902 to call a conference of that service when requested officially by the health or quarantine officers of any five States. The principal object of this conference will be the consideration of bubonic plague in San Francisco and in the State of Sinaloa, Mexico.

A Lowered Death Rate in New York City.—In the annual report of the Health Department the announcement is made that the death rate of New York for 1902 was 18.74 per 1,000, which is considerably the lowest ever reported in this city. The total number of deaths was 68,082, as compared with 70,803, and a death rate of 20.02 per 1,000 for 1901, which is a decrease in the rate of 1.28 per 1,000, and indicates a saving in 1902 of 4,619 lives. The death rate for 1902 in each of the five boroughs was also the lowest on record. The annual death rate of the city since consolidation has been as follows: 1888, 20.26; 1889, 19.47; 1900, 25.97; 1901, 20.02; 1902, 18.74.

An International Medical Congress at St. Louis.—The authorities of the Louisiana Purchase Exhibition at St. Louis have taken steps toward the organization of an international medical congress, to be held in 1904, by appointing an executive committee composed of Drs. W. G. Moore, F. J. Lutz, H. Tuholske, W. E. Fischel, and L. H. Laidley.

The Beth Israel Hospital.—About $25,000 was realized for the benefit of the Beth Israel Hospital at a fair and reception in Madison Square Garden two weeks ago.

Obituary Notes.—Dr. A. M. Tully died November 4, 1902, at Las Vegas Hot Springs, N. M., at the age of forty-eight years. He was a graduate of the Medical Department of the University of Vermont in the class of 1880, and practised his profession for fifteen years in Chicago. For several years he was on the staff of General Crook.

Rontgen Rays in the Causation of Cancer.—The death of Dr. Blacker, who cured the king of a rodent ulcer and soon afterward himself died of epithelioma, was even more tragic than in a previous letter it was described to have been. There appears to be reason to believe that the disease which caused his premature death was due to *x*-ray dermatitis. While manipulating the apparatus, he is said to have received a severe burn on one of his fingers; the dermatitis gradually spread up the arm, and in its track malignant growths developed, first near the elbow and afterward in the axilla, finally involving the whole of the shoulder. Amputation at the shoulder joint was contemplated, but the rapid extension of the disease deterred Sir Frederick Treves from attempting operative intervention. I hear that this is not the only case in which the origin of malignant disease has been traced to the *x*-rays.—*Medical News.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CHRISTMAS IN HOSPITAL—MUNIFICENT DONATIONS—PROFESSOR BALL—SMALLPOX—COLLEGE OF PHYSICIANS—TYPHOID FEVER AND SHELL FISH—MAJOR ROSS—PATHOLOGY OF PANCREAS—SPASMODIC ASTHMA.

London, December 26, 1902.

Yesterday being Christmas day, the patients in the several hospitals were entertained as usual by the students, staffs, and nurses. For those who could take them, little dietary extras were provided, and in the evening the wards were decorated, and music and other amusements kept up. The inmates of workhouses and charitable institutions of all kinds were similarly treated by benevolent persons.

The Lord Lieutenant of Ireland has intimated his intention to confer a knighthood on Mr. C. B. Ball, Regius Professor of Surgery in Trinity College, Dublin. Professor Ball was the operator on Her Excellency, the Countess, as I have already reported to you. He is the youngest son of the late Robert Ball, M.D., the eminent naturalist, and a brother of Sir Robert Ball, the professor of astronomy at Cambridge.

The Hospital for Sick Children is the recipient of £50,000, from Mr. W. W. Astor, for building a new outpatient department, to be dedicated to the memory of his little daughter Gwendoline, who died in the autumn.

Mr. Astor's munificent gift is of special value just now, for the committee has been exercised for a long time on the inefficient state of the department, which might well be called disgraceful, and which has more than once been complained of by the visitors of the King's Hospital Fund

The Chelsea Hospital for Women has just received £1,000 from the executors of the late F. T. Freeman.

The Royal College of Physicians has had its adjourned discussion on the propriety of retaining Latin as a subject for preliminary education. The ancient corporation came to the conclusion to pass on to the next business—thus giving us another instance of its incapacity. The whole discussion displayed a nervous fear of disagreeing with the University of London, some of the graduates of which are advocates of German. They seem to forget that the Germans do not ignore Latin, and that there is an air of unreality about all these discussions. It is nonsense to say that Latin is useless unless carried to the degree of ripe scholarship.

Smallpox is officially announced to be spreading in Liverpool. The outbreak threatens to be more widespread than that of last winter. An appeal has been issued urging revaccination.

The oyster merchants have been roused to renewed activity by the recent pollution of the Emsworth beds. They appointed a committee which met at Fishmongers Hall and collected evidence to prove that other beds were free from sewage contamination, and none but those of clean origin were admitted to the London market. Every facility is afforded to inspectors of the Fishmonger company and the city corporation. They ask for legislation. It is not only oysters, but all shellfish which ought to be protected. A recent outbreak of typhoid fever at the East End of London was confidently attributed, by the Medical Officer of Health, to the consumption of cockles at Southend by holiday makers. Whether this were so or not, there is no doubt that the cockles were taken from beds below the outfall of sewage works. The Local Government Board is well acquainted with the position—its own inspectors have warned it of the danger, but nothing is done. What is the use of a government board which merely fills a blue book with proofs of the necessity of doing something, and then does not do it?

Major Ronald Ross, C.B., F.R.S., was entertained on Monday at an "at home," in the town hall of Liverpool, given by the Lord Mayor and Lady Mayoress. The Nobel Prize being awarded to Major Ross for his discoveries in reference to malaria was made the occasion of this local honor, in which the Liverpool Tropical School largely participated.

Sir M Foster, who had intimated his intention to retire from the representation of the University of London was subsequently reported to have reconsidered his decision. After that the papers declared his committee had not received any such decision. "First she would and then she wouldn't."

An intensely interesting research on the pancreas, by Professor Starling and Dr. W. M. Bayliss, was the subject of a communication to the Pathological Society. The

primary object of the investigation was physiological, but some of the results have a pathological and clinical bearing. Indeed, this research must be taken into account in any proposed pathology of the pancreas. C. Bernard showed that the introduction of ether into the stomach produced a flow of pancreatic juice. Then Pavlov showed that food or acid must pass into the duodenum before the secretion began. Drs. Stirling and Bayliss now find that the introduction of acid into the upper part of the small intestine causes a flow of pancreatic juice. They isolated a portion of jejunum from all its nervous connections, and found the flow equally excited by the acid. The action, therefore, seems chemical—certainly not reflex. They scraped the epithelium from the jejunum, pounded it with acid, and injected it into the veins of an animal. This caused a large flow of juice. In the cells of the intestine must be the substance, which, reaching the pancreas through the blood, excites the secretion. For this substance they propose the name "secreton," which will, at any rate, serve to distinguish it for the present. This "secreton" is identical in frogs, birds, and mammals; it always, when injected, produces a flow of pancreatic juice. Three ferments occur in pancreatic juice, acting respectively on proteids, carbohydrates, and fats. Juice collected from a fistula has a strong action on fats, but only a weak one on proteids; if allowed to flow over the mucous membrane, the proteid action is greatly increased. So collected from the duct, it has no tryptic action, but the addition of scraped mucous epithelium from the intestine makes it powerfully tryptic. The juice must, therefore, contain trypsinogen, and needs only something contained in succus entericus to produce the tryptic ferment. This something is called "enterokinase." Injection of "secretin" stimulates the pancreas, even when there is no acid in the duodenum; in that case, intense congestion of the mucous membrane is produced. While pancreatic juice remains in the ducts, it has no action, as there is no carbohydrate and very little fat present, and the tryptic ferment is inactive without entorokinase. Regurgitation of succus entericus into the pancreatic ducts would produce the tryptic ferment, and this might set up acute pancreatitis.

In the discussion on the paper it was remarked that gastro-enterostomy had not been followed by such ill results as might be expected from the facts related—thus it might lead to enteritis with atrophy or necrosis of intestinal epithelium. Professor Starling, on this point, said secretin was not produced in the lower two feet of the ileum, and if the gastric communication was made so low, he should expect pathological results.

Drs. T. G. Brodie and W. E. Dixon recently had a paper at the Pathological Society, upon some points concerning spasmodic asthma. All the symptoms of an attack, they admit, can be explained by the common view that they are caused by contraction of the muscular walls of the small bronchioles. The innervation of these muscles was, therefore, first considered. Experiments were described, and tracings shown illustrating various points. One point may be named—there is no evidence that a local irritant is present in the attacks.

The results of experiments with drugs may, perhaps, be most interesting to your readers. Some, *e. g.* muscarine, pilocarpine, physostigmine, produce constriction by acting on the nerve ends. Others, *e. g* barium, bromine, chloride of gold, etc., by acting on muscles. The effect of the first can be neutralized by atropine.

Those acting on muscles, however, are not affected by this drug. This action of atropine is noteworthy, as the drug has often been employed with success, although a sufficient dose cannot be given to control the spasms. Another drug clinically in repute, is lobelia, and the experiments showed that it has a distinct effect; injected into an animal to annul the bronchial spasm produced by muscarine, or pilocarpine, it caused dilatation, but this lasted for only one or two minutes, when the spasm returned.

With regard to other points, nothing like an asthmatic attack had ever been produced by stimulation of the nasal or gastric, or intestinal mucous membrane.

Rectal Feeding in Febricula and in Typhoid Fever.—Emilio Cioffi holds that rectal feeding is the ideal method in both of these fevers. The stomach is given complete rest, and there is no danger of any food reaching the small intestines, which are the seat of ulceration and which, therefore, should be protected from all irritation. Milk, eggs, and peptones are used in the nutritive enemata, and by their use the author has taken many cases successfully through the disease, completely avoiding the vomiting which is so dreaded, especially in typhoid fever.—*Giornale Internazionale delle Scienze Mediche*, December 15, 1902.

THE FIRST EGYPTIAN CONGRESS OF MEDICINE.

(From Our Special Correspondent.)

CAIRO, December 26, 1902.

MODERN Egypt is not the country to which the American or European medical man would look for much enlightenment in the practical needs of his profession. And yet Egypt cannot fail to interest him, not only as the land which may be regarded as the ancient home of medical and surgical knowledge, but also because, at the present day, it is subject to many strange pathological phenomena. It is, above all, the home of that peculiar African disease, bilharziosis; and ankylostomiasis, pellagra and ophthalmia are, like the poor, always with us. Its geographical position alongside the great world thoroughfare—the Suez canal—which links the East to the West, and its nearness to Mecca, to which large numbers of its inhabitants annually go and collect the infection of the whole Mussulman world, afford the sanitary authorities of Egypt but too many opportunities for becoming familiar with cholera, bubonic plague, and other infectious diseases. It is not uninteresting to remark on the almost complete absence of scarlet fever, whooping-cough, and amyloid degenerations in this country. As an example of the efficacy of vaccination in stopping the ravages of small-pox, no country presents a more striking example than Egypt. In a land which is essentially Mohammedan, alcoholism does not loom so largely as it does in most other countries; but, on the other hand, the wide use of hashish as an aphrodisiac, produces a very large number of cases of neurasthenia and insanity, as Dr. Warnock has shown at this congress. A weekly mortality of 200 from infantile diarrhœa, of fourteen from enteric fever, and three from scorpion bites; and the extraordinary freeness of this semitropical country from malaria, except on the borders of that great highway for malaria-stricken patients, the Suez canal, complete this rough sketch of the salient pathological features of the land.

It was only natural, when these facts were taken into consideration, that this congress should have attracted chiefly those interested in the diseases of warm climates and a few others attracted by the fascinations of this bizarre part of the earth. Official delegates were sent from most of the European and neighboring Eastern countries, from America and from Australia; but the majority of the visitors, not unnaturally, came from the shores of the Mediterranean, where the diseases of Egypt present a more genuine, because a nearer interest, than they do elsewhere.

The congress was opened by his Highness the Khedive Abbas Hilmy II in the Opera House, Cairo, on December 19, 1902, in the presence of the ministers of state and all the diplomatic representatives. On the succeeding four days the scientific sittings were held in the magnificent lecture-rooms of the Egyptian Government School of Medicine which had been lent for the purpose. The number of communications (236) was so great and the sections so few (Medicine, Surgery, and Ophthalmology) that little opportunity was offered for proper discussion. Demonstrations of interesting cases—chiefly bilharziosis, pellagra, and leprosy—were given daily in the Kasr-el-ainy Hospital which forms part of the School of Medicine.

During the congress nothing aroused more interest than the splendid collection of nearly 900 pathological specimens, almost all retaining their natural colors with unimpaired brilliance. These specimens were collected and prepared by Dr. St. Clair Symmers, Professor of Pathology. In this museum the bilharzial preparations attracted most attention by reason of their novelty, and also by their graphic demonstration of the whole course and the many manifestations of this, the commonest disease in Egypt. In one specimen of the urinary bladder could be seen a small area of light-brown or sandy discoloration (microscopically found to be crowded with ova of bilharzia hæmatobia) representing the earliest phase of bilharziosis; a series of more advanced stages culminating in specimens in which the whole mucous membrane of the bladder was "sandy" or, in others, had budded out into large papillomatous growths (studded with ova) which might block up the openings of the ureters or urethra or completely fill the bladder; other specimens showed the infection or the secondary changes in the ureters and kidneys.

Other specimens showed exactly analogous phenomena in the rectum, colon, and intestines; in some cases forming tumors which might be mistaken for cancer; in others causing multiple ulcers, which were a common cause of "dysentery" in Egypt.

Other specimens again showed similar changes in the female genital organs, vulva, vagina, uterus, Fallopian tubes, and ovary. There was a cauliflower-like bilharzial growth from the cervix uteri, which was mistaken for

cancer and led to hysterectomy. Another specimen—bilharziosis of the vulva—was probably unique, because the papillomata contained not only the ova, but also the worms themselves.

Other specimens showed the peculiar periportal variety of hepatic cirrhosis, which Professor Symmers had recently discovered to be due to this disease.

At the first meeting of the Surgical Section all of these specimens were shown and described by Dr. Symmers. On the same occasion Professor Looss (of the Egyptian Medical School) brought forward a number of new facts concerning the life-history of bilharzia. He clearly demonstrated the manner in which the spine of the ovum was formed by the chitinous capsule adapting itself to the shape of the uterus, the spine being chitinous material which protruded into the efferent canal (vagina). Hence, the different position of the spine (whether terminal or lateral) had no other significance than an indication of whether the ovum was placed vertically or obliquely in the uterus. Professor Looss also gave it as his opinion that the bilharzia larva could enter the human body only through the skin (during bathing), as he had clearly demonstrated in the case of uncinaria (ankylostoma). He could adduce no direct proof; but the fact that the larva was instantly killed by gastric juice and dilute hydrochloric acid proves that it was impossible for it to enter the body through the alimentary tract. In the discussion which followed, Dr. Ruffer objected that the infection of bilharziosis in the Transvaal could not be explained in this way, because bathing was not such a common habit there as it is in Egypt; to this Professor Looss replied that all the local authorities in South Africa could explain the transmission of the disease only in this way.

Dr. Ruffer also attempted to combat the view that the ova of bilharzia formed a common nucleus of urinary calculi (which are so common in Egypt) by the statement that he had been unable to find the ova. Professor Looss pointed out that once the technical difficulties had been overcome, and the necessary experience attained, bilharzia-ova could be certainly demonstrated in a very large proportion of the calculi found in Egypt.

A large number of papers were read on the clinical aspects and treatment of bilharziosis, but these were of purely local interest. The statements and the microscopical preparations of Dr. Goebel (Alexandria) failed to convince his hearers as to the carcinomatous nature of some of the renal and vesical bilharzial lesions.

Dr. Symmers also showed an enormous cavernous angioma of the liver, the organ being three times the normal size, and at least seven-eighths of the whole being transformed into cavernous tissue. This specimen was probably unique.

It was also pointed out that, in spite of the habits of the people, echinococcus was exceedingly rare in Egypt; and, as in Australia, amyloid disease was hardly ever found, "notwithstanding the enormous amount of syphilis and tuberculosis."

A series of cases of both the red and the black varieties of madura-foot were shown. Dr. Symmers also showed specimens of severe bronchopneumonia, which was an exceedingly common cause of death among foundlings (most of whom are syphilitic) in Cairo.

He also showed three specimens of elephantiasis of the scrotum, in one of which the bulk of the tumor was composed of fat, another of exceedingly dense fibrous tissue, and in the third the scrotum exhibited dense fibrosis and in parts mucoid degeneration.

Professor Looss exhibited a very large collection of intestinal parasites obtained from man and other vertebrates in Egypt; and also gave demonstrations of the life history of ankylostoma duodenale, and of the manner in which the larvæ make their way through the unbroken human skin.

The extraordinary collection of desiccated bodies of prehistoric Egyptians in the Anatomical Museum of the School of Medicine aroused great interest during the congress. The brains, eyes, hair, skin, and various viscera of these people of 7,000 years ago were shown, as well as many pathological specimens—osteitis deformans, dental abscesses, bone-lesions of doubtful nature, variously attributed by different experts to syphilis, tubercle, elephantiasis, etc. The earliest known splints (used for fractures of the femur and radius and ulna) were shown, as well as many reunited fractures, and an unreduced forward dislocation of the knee with new-joint-formation. The earliest renal calculi ever found were shown and also a prehistoric prolapsus ani. Various mutilations of the genital organs (from the Soudan) were exhibited

The study of these various museums in the School of Medicine may be regarded as the chief work of the congress.

The memoirs presented to the congress may be divided into two classes: (1) those of a general nature and (2) those of chiefly local interest.

In the first group the most noteworthy was perhaps the oration delivered at the opening ceremony by Professor Bouchard (Paris) on the new tendencies in therapeutics. This consisted in an advocacy of the views (already stated in part in *Comptes Rendus de l'Académie des Sciences*, July 7, 1902) that the local manifestations of certain general diseases may be more effectively treated by the local application of the appropriate drug in minimal doses than by the mere general exhibition of the medicine. For example, if a man of sixty kilos weight suffering from acute rheumatism which chiefly affected one joint received each day six grams of salicylate of sodium by mouth every kilo of his body received ten centigrams of the drug: in other words, not only the diseased part but also the healthy part of his body was receiving this chemical which, if not directly harmful, could serve any useful purpose in the healthy tissues Why not, therefore, inject five or ten milligrams of salicylate of sodium locally into the 50 or 100 grams of soft tissues around the joint? Experience showed that such treatment, even by extremely minute doses (applied locally), was more effective than a proportionate dose per os. General treatment, however, was obligatory; but if it showed itself insufficient local medication was a most efficient and valuable aid. In the treatment of syphilis, and especially in the case of gummata and painful local troubles, the local injection of minimal doses of mercury and iodide had proved most efficacious. Either drug might be used separately, or 2 c.c. of a solution containing one centigram of perchloride of mercury and three grams of iodide of potassium to 100 grams of water might be employed.

Book Reviews.

A Manual of Surgery for Students and Practitioners. By William Rose, M.B., B.S., F.R.C.S., and Albert Carless, M.S., F.R.C.S. Fifth edition. New York: Wm. Wood & Co., 1902.

The essentials of a good textbook should be a clear, concise statement of the main facts of the subject with which the volume deals. The reviewer knows of no book in our language which satisfies these conditions better than does this manual, and the issuing of five editions within four years is proof of its merits and popularity. A criticism of the several parts of this general textbook is hardly the purpose of this review. The authors have not attempted to present any new facts. They have tried and admirably succeeded in furnishing to the student an up-to-date, reliable, concise textbook. The volume is very nicely made up; its printing clear and sharp, and the text is amplified with numerous excellent illustrations. The work is well written in a brief, clear style, and the illustrations are well chosen, instructive, and not too numerous. The publisher has made the text into a very attractive book, which deserves to meet with good support on the part of students and medical book buyers.

Manual of Antenatal Pathology and Hygiene of the Fœtus. By J. W. Ballantyne, M.D., F.R.C.P.E., F.R.S. Edin. New York: William Wood & Company, 1902.

The name of Ballantyne is so intimately associated with the studies of antenatal conditions that anything from his pen will be cheerfully welcomed. In this volume the author describes fetal physiology and pathology and announces a second volume on teratology and morbid heredity. When we consider the vast opportunities for detailed study—according to the author, "nearly 300 specimens, embracing almost all the leading types of antenatal morbid states"—then our interest in the work is increased.

In glancing through the pages we find chapters that are so important to the general practitioner that they deserve at least a word. For example, concerning "Fractures of the Long Bones," and "Dislocations in the New-Born Infant." "Sepsis Neonatorum" is a very interesting article. The description of "Fetal Growth" is very interesting. The ever welcome chapter on "Fetal Syphilis" is very important. The chapter on "Fetal Endocarditis" is worthy of note. So we go from page to page until the chapter on "Antenatal Diagnosis" is reached.

These are only a few of the many instructive chapters—all written in a clear, distinct style, and bringing out point after point in conformity with modern thought. The book is profusely illustrated. There are over 500 pages of instructive reading matter, with a very complete index. The author is to be congratulated on his excellent work, which will add laurels to his well-deserved reputation.

Progress of Medical Science.

The Boston Medical and Surgical Journal, January 8, 1903.

Plague Serum in Three Cases.—W. J. Calvert used plague antitoxin in three cases of the disease in Manila. One case recovered, and in this case 200 c.c. of the serum were injected. The author believes that if larger doses had been given in the other cases more favorable results might have been obtained. The points of interest in the first fatal case were left lower pneumonia, enlarged spleen, left femoral bubo, and marked septicæmia on the third day before death. In the second case they were severity of the attack, right femoral bubo, with involvement of all inguinal glands, and septicæmia from the second day of disease until death. In the first case very few bacilli were found in smears from the blood and spleen, but many in smears from the consolidated lung and the bubo. In the second case a few bacilli were found in the blood and spleen, while smears from the bubos were teeming with organisms.

The Malignancy of Joint Tuberculosis Illustrated by a Series of Forty-seven Cases.—Charles F. Painter, from his study of the subject, reaches the following conclusions: Tuberculous disease tends to recur after apparent cure in a considerable proportion of cases. This recurrence is most commonly a local one. Metastases are not common. Trauma, direct or indirect, is frequently associated with the recurrence. Indirect trauma is probably the exciting cause of the recurrences, especially when partial ankylosis or deformity exists. Patients who have suffered from bone and joint tuberculosis should be cautioned that they are not well when symptoms have ceased, and that reasonable care must be exercised to avoid recrudescences. Deformity and shortening should be corrected as far and as accurately as possible, to lessen the chance of recrudescence. Mechanical treatment, especially fixation, should be used in the acute conditions in childhood. Exploratory interference, where discretion is used, with the view to removal of isolated foci, is advisable in many cases in children, and is to be urged in the majority of recrudescences if seen early. Recognition of the fact that patients with hip disease, Pott's disease, and tumor albus have tuberculosis just as much as if they had phthisis, and should be treated accordingly, must be insisted upon.

Journal of the American Medical Association, Jan. 12, 1903.

The Relations of Lupus Erythematosus to Tuberculosis.—The conclusions offered by H. G. Anthony are as follows: (1) That discoid lupus erythematosus is a granuloma, which has no relation whatsoever to tuberculosis, but which may be accompanied by a general eruption. (2) That tuberculosis may produce symptomatic lupus erythematosus, usually with disseminate, atypical plaques. (3) That what may be shown by statistics regarding the relation of lupus erythematosus to tuberculosis depends on what is understood as evidence of tuberculosis, and also on what is included in lupus erythematosus.

Peripheral Neuritis as a Complication of Whooping Cough.—A. A. Eshner refers to previously reported cases of this association of lesions, seven in number, omitting those characterized optic neuritis and deafness. The cases include paralyses of the lower limbs, the cricoarytenoid muscle in the larynx, upper extremities, neck, diaphragm, etc. In some the paralyses were permanent, but the majority recovered. Coincidently with the motor lesions, the sensibility may or may not be impaired. The functions of the rectum and bowels are generally unaffected. The details of symptoms do not materially differ from those of neuritis due to other causes.

Tuberculous Peritonitis.—This topic is considered by T. M. Rotch with special reference to the occurrence of the disease in early life and its treatment by laparotomy. Sixty-nine cases are carefully analyzed, the analysis showing that tuberculosis of the mesenteric lymph nodes does not preclude a successful result in treatment. It also shows that, inasmuch as the presence of palpable masses and the absence of fluid does not preclude a successful operation, and inasmuch as the degree of intestinal adhesions can only be surmised before operation, laparatomy would seem to be indicated in all cases of tuberculous peritonitis, provided (1) that the general condition of the patient permits it, and (2) that there is an absence of evidence of cerebral, pulmonary, or extensive glandular or bone tuberculosis. The presence of tuberculous ulcers of the intestines is obviously an unfavorable condition for operation, but in many cases they cannot be diagnosticated by the clinical symptoms. Of 20 cases operated on and relieved, the history of 13 was traced; 1 had died 4 months after operation, 1 lived 7 months, 1 was well for one year, but then relapsed, while the remaining 10 were alive and well at periods after operation varying from three months to nine years. The symptoms observed were as follows: Abdominal tenderness was generally absent, and if present was rarely severe. The movements of the bowels, so far as recorded, were not significant, loose movements and constipation alternating, and one being about as frequent as the other. Even in the cases in which an autopsy subsequently showed the presence of tuberculous ulcers of the intestines, there was, as a rule, nothing especially characteristic or suggestive noted in the discharges. The temperature was, as a rule, elevated and irregular. Pulse and temperature accelerated and variable, while the presence or absence of leucocytosis seemed to be of very little value in either diagnosis or prognosis.

Medical News, January 10, 1903.

Intermenstrual Pain.—Jennie G. Drennan states that in these cases the pain occurs from the twelfth to the sixteenth day from the commencement of the preceding menstruation; in some cases it is paroxysmal, or, again, the pain is constant with very severe exacerbations. It ordinarily lasts two days. In none of the cases recorded was there a menstrual discharge, but an increased amount of leucorrhœa was observed. The writer obtained good results in one case by merely treating the general condition. She believes that there was a spasmodic contraction of the cervix uteri—internal os—due to extreme excitability of this organ in a neurotic patient at the time when the unimpregnated ovum was being cast off from the uterus. Another theory is that: "intermenstrual pain" is a Fallopian tube colic.

Veratrum Viride as an Antitoxic.—A. B. Isham gives the history of a number of cases successfully treated by subcutaneous injections of veratrum viride. These patients suffered from a variety of affections: eclampsia, pneumococcus infection, pulmonary tuberculosis, convulsions (carbolic-acid poisoning), contracted kidneys (uræmia), gallstone colic, thermic fever (acute delirium), convulsions (opisthotonos). The writer declares that the properties by virtue of which veratrum viride antagonizes toxæmia are largely inherent in its active principles, or alkaloids, jervia and veratroidia. Both alkaloids are said to "depress the functions of the spinal cord" and to abrogate its reflex activity without affecting the irritability of nerves or the contractibility of muscles. Jervia, in sufficient doses, causes salivation, slows the action of the heart and lessens arterial blood pressure. In large doses it causes convulsions and death from asphyxia. Veratroidia has a feebler action than jervia upon the cord cells. It always causes vomiting, and sometimes purging. In large doses it causes convulsions, less severe than in the case of jervia, and death from respiratory paralysis; it reduces the frequency of the pulse. In small doses it increases the force of the heart, but in larger doses weakens it and lessens arterial pressure. Frequently, copious perspiration follows the exhibition of both alkaloids in adequate amount. The liver cells are stimulated, and the secretions of accessory glandular organs are excited to unusual activity.

Boiling as a Method of Sterilizing Catheters.—C. B. Nancrede and W. H. Hutchings conclude that: (1) Although the washing with warm soap-suds is an absolute prerequisite to most methods of chemical sterilization and is an excellent precaution, in the method of employing caloric recommended by the writers, it is not necessary, as their experiments have shown. (2) One of the chief obstacles in the way of catheter sterilization has always been the oily lubricants. The boiling temperature promptly liquifies the vaselin usually employed, which will be seen floating upon the surface of the fluid, mechanically carrying away with it numerous germs mingled or adherent to the cold, semi-solid lubricant. (3) The English catheter is more readily sterilized than the soft-rubber instruments, and can be repeatedly boiled without material damage, with proper precautions. (4) The English web catheter can be boiled for any length of time without damage in a saturated solution of ammonium sulphate. As this boils at 104° C., it is superior to plain water, but subsequent washing in sterilized water is requisite to remove crystals of the salt which are deposited on cooling. (5) The only precautions requisite in boiling English catheters in plain water are those necessary to prevent their coming directly in contact with the bottom of the vessel in which they are boiled—this can be done by enveloping them in gauze or a towel. (6) The authors' numerous experiments incontestably prove that caloric can be successfully employed for all varieties of catheters with the exception of the soft French instrument, provided all air is expelled from the interior; that this essential having been secured, although in a great majority of cases five minutes' immersion in water which is actually boiling will suffice, ten minutes of actual ebullition should be employed, especially

for the smaller-calibered instruments; and that a previous cleansing with warm soap-suds is desirable, although not essential, reducing, as it does, the time of exposure requisite to sterilize the instruments.

New York Medical Journal, January 10, 1903.

A Case of Tetanus Following Vaccination.—The case is reported by W. S. Cooke, the patient being a girl of four years. An older sister, vaccinated at the same time, had no untoward result. Four weeks later the patient began to have some pain and stiffness in the facial muscles, and three days later a typical spasm occurred in the abdominal muscles, the entire body gradually becoming affected in the recurring seizures. There was at first no opisthotonus. These seizures continued at intervals for over a week, but gradually subsided. Antitoxin was injected on several occasions. Other than this the treatment consisted of potassium bromide and chloral two grains and a half of each to the drachm of mixture, every two hours, and later every hour; the antitoxin, as stated, and whiskey in two-drachm doses, every two hours. Laxatives were used only twice, and the nourishment was entirely liquid, mainly milk. As to the cause of the infection, the author states that he followed the usual measures as to surgical cleanliness, etc., while a shield was worn. The child was sent to the country shortly after the vaccination, and it is probable that, during her out-door play, dust and dirt-carrying tetanus germs settled on her legs (the site of vaccination), and that perspiration washed the infecting material into the sore.

Note on the Salt Starvation Principle in Epilepsy; Treatment by Bromides.—L. P. Clark says that it has been found that bromine can replace chlorine in the tissues. Therefore, by sodium chloride starvation and the continual administration of the bromides, we get an organic bromide compound acceptably fulfilling the physiological rôle of chlorine, and, at the same time, acting as a therapeutic agent of sedation in epilepsy. Ordinarily we know the dosage of bromide sufficient to control epileptic seizures is from 60 to 160 grains, but under the salt starvation method 20 to 60 grains is just as efficacious. The lowering of the dosage means a lowering of the possible toxicity from the drug, with its well-known attendant evils upon mind and body. Then, too, the economic feature of the plan is obvious, as bromide sedation in epilepsy, as well as in other neuroses, must often be continued for several years. It is especially to be recommended in those acute idiopathic cases which require such large doses of bromides given in the ordinary manner that fatal intoxication is imminent; in those in which even unusually high dosage of bromide is of little value; in those totally intractable to the bromide salt; and, finally, in all chronic cases in which a long-continued sedation is necessary to hold in partial check the severity and frequency of epileptic attacks. The dietary should be especially arranged for palatableness, and consist of cereals, milk, and vegetables. The bromide of sodium should be given in the patient's food in place of table salt, as it is nearest like the latter.

Thoughts on Fetal Intracranial Hemorrhage.—D. H. Stewart believes that this accident arises from unequal squeezing. That is, a lack of counter-compression on the vertex simultaneously with heavy urging pains acting on the body. This causes increased tension in the intracranial vessels, and happens under certain conditions and at a definite stage of labor, the forceps in the majority of cases being applied too late or not at all. The accident may occur without the formation of any caput. succedaneum. The period of danger of liability to hemorrhage is the interval between rupture of the membranes and complete pelvic engagement. A heavy pressure on the body in a dry labor before overlapping, especially if there is constriction of the veins of the neck by an encircling cord, is a fairly certain cause of cerebral engorgement. To prevent this accident we should in dry labor dilate the os promptly, and furnish pressure against the vertex with the rubber dilator. As soon as possible, the forceps should be applied and the head brought low, so that the bones along the sutures will lap and keep their places. Lateral pressure in undesirable, unbalanced, and intracranial pressures are the dangerous ones. To determine the existence of this accident the author lays down the following rules: When the child is born, feel the fontanelles with the palmar surface of the finger, never with the point; and have the contact as extensive as possible—pulsations are made out quite clearly in this manner. Lay the palmar surface of the little finger along the arched top of the tongue. If there is either tremor or rigidity, the clot is at the base. Here there is usually no attempt at sucking. There may or may not be in vertex cases, although sucking well on the second or third day is no disproof. Rigidity of the jaw is rare. A peculiar convergent strabismus (clonic) is common. It gives good ground for a fatal prognosis if it lasts more than a few minutes. It is also found after burns in the new-born, and if it begins, it usually continues till coma and death take place.

American Medicine, January 10, 1903.

Secondary Hemorrhage of the Umbilicus.—Ramon D. Garcin delivered a patient of a healthy boy on October 23. The case progressed satisfactorily, the cord coming off on October 29. There had never been any oozing, and the surface underneath was smooth and healthy. On October 31 there was secondary hemorrhage of the umbilicus, due to detachment of a clot of blood over the seat of the artery. The child died in a few minutes.

The Causes of Death in Diphtheria.—Bernard Kohn states that it is in cases of mixed infection that the severe complications of diphtheria are most likely to occur. Of these, bronchopneumonia is the one most to be dreaded. It occurs especially when the larynx is involved. The kidneys are more or less affected in almost every case of diphtheria of moderate severity, but the nephritis usually runs a favorable course. A distressing mode of death, from the physician's standpoint, is that due to heart failure. It may occur early or late; in cases of great severity, or in the mildest cases. Occasionally death from heart failure may occur without warning or previous symptoms, but usually, if carefully watched, there will be noted some premonitory symptoms. In some cases of sudden death, apparently from cardiac paralysis, there may be found a hyperplasia of the thymus gland, lymph nodes, spleen, and other lymphoid tissues, associated with a hypoplasia of the heart and the aorta. These changes form what is called the "lymphatic constitution." Changes in the nervous system due to the action of the diphtheric poison are frequently noted. Finally, diphtheria may be complicated with other infectious diseases, such as measles, scarlet fever, or typhoid fever. In many cases the combinations are most deadly.

The Treatment of Epilepsy by the General Practitioner.—William P. Spratling declares that epilepsy is curable in many cases if taken in time, and if accurate treatment is given for a sufficient length of time. The writer summarizes the principles of treatment as follows: (1) Every patient should be searchingly examined, to bring to light the especial cause in each case. Then the patient and his disease should be treated as a unit, never being disassociated. For example, the bromides should not be given simply for the fits while nothing is done for the individual whose moral and physical stamina is so often impaired. A dietary should be written out for each case, to be strictly followed. The writer believes that, unaided, bromides never cured a case of genuine epilepsy. If the bromides are given, it is best to employ either the hypochlorization method or to use bromipin, which is a 10-per-cent. solution of pure bromine in the oil of sesame. This does not produce acne, or impair the digestive or assimilative functions, nor does it suppress or pervert any of the faculties or functions of the mind or body. In the form of an emulsion it is a very good reconstructive. Every defect or ailment that can be discovered should be combated with appropriate treatment. The patient should be mentally and physically employed all the while, and not allowed to think he is an invalid. After several years of this treatment, the results will prove gratifying.

Philadelphia Medical Journal, January 10, 1903.

The Parasyphilitic Affections; the Curability of Tabes and General Paralysis by Intense Mercurial Treatment.—Leredde declares that, after having cured a case of tabes with mercurial treatment, after thorough researches upon the parasyphilitic affections, and cases of recovery from tabes and general paralysis, he is absolutely convinced that in syphilitic patients these diseases are not only syphilitic in origin, but can also be cured by mercurial treatment if the mercury be pushed to very high doses. The unsuccessful cases are due to incorrect treatment, and to the existence of the irremediable degenerations produced in these conditions, as in all other affections of the nervous system. When the day, which is not far distant, arrives when the syphilitic nature of tabes and general paralysis will be admitted as a demonstrated truth, the histologists will have to describe the lesions of syphilis in a broader manner.

What Can Be Done to Lessen the Mortality of Carcinoma Uteri?—E. E. Montgomery believes that neglected lesions of parturition are a prolific source or cause for the development of carcinoma of the cervix uteri. These lesions, then, should always receive attention. Next to prevention is the early recognition of the disease. There are no characteristic signs of cancer of the uterus, nor is the disease limited to any particular period. The three symptoms upon which the diagnosis is based are pain, hemorrhage, and discharge. But, unfortunately, these

symptoms are found in other conditions, and are not regular in their occurrence in carcinoma. The pain is usually lancinating. Hemorrhage is a danger-signal, as is also a discharge, thin and watery, with a sweetish, fetid odor. The mortality can be lessened by early operation in healthy tissue, and, with the exercise of precautions, to prevent the re-implantation of the disease. Generally the abdominal incision is preferable to the vaginal, as by it the operator is enabled to go further away from the involved structures.

Deutsche medicinische Wochenschrift, December 11, 1902.

Congenital Elephantiasis.—L. Bernhard and M. Blumenthal report a case the clinical picture of which is identical with that of the acquired form of this disease. In addition to the diffuse fibromatous increase of connective tissue, small lymphangiectases were present in large numbers. Without microscopical examination the diagnosis of elephantiasis would have been impossible. The etiology could not be explained on the basis of hereditary influences. or inflammatory lesions. Bacteriological examinations were also negative. It seems probable that the condition should be considered a lymphangioma due to anatomical malformations of the lymphatic system.

Epithelioma Contagiosum of Birds.—E. Marx and Anton Sticker's experiments show that none of the organisms which have hitherto been regarded as the cause of this disease bear any etiological relation whatsoever to the same. The virus of the disease belongs to the filtratable poisons, as it readily passes through a Berkfeld filter. It is very resistent, surviving drying and exposure to the day and sunlight for several weeks. It is still active at 12° C., and is not destroyed by a three hours' heating to 60° C., or one hour at 100° C., provided it has been previously dried and placed in a sealed vacuum tube. It is more susceptible to the action of carbolic acid, which kills it in a two-per-cent. solution. The virus of dove-pox if passed through the hen becomes incapable of producing the disease when reinoculated into doves. One attack of this disease always confers a complete immunity.

A Mercurial Reaction Peculiar to Syphilitics.—Karl Herxheimer and Dr. Krause describe a cutaneous mercurial reaction which occurs only in syphilitics, and which may be utilized for diagnostic purposes. It only occurs when the mercury is given by inunction. In from fifteen to twenty-four hours after such a treatment, in case no eruption is already present, there appears over various regions of the body a more or less diffuse redness, which gradually increases in intensity for about twelve or twenty-four hours, and then slowly subsides, until it finally disappears. In cases in which an eruption is already present, this increases in redness, becomes elevated and more or less confluent. Numerous observations have shown that in normal individuals and those sick with other diseases this reaction never occurs. Perhaps its greatest value is in the early diagnosis of syphilis, but it may also be used in differentiating tertiary lesions. Furthermore, the intensity of the reaction is of prognostic value, for its intensity stands in direct relation to the amount of syphilitic poison present in the system, and hence gives a guide to the exact condition of the patient from a syphilitic standpoint.

Deutsche medicinische Wochenschrift, December 18, 1902.

Inherited Diaphragm of the Larynx.—P. Fraenckel adds two cases to the literature of this rare condition. The first patient was twenty-two years of age, and had suffered with constant hoarseness and frequent attacks of laryngitis from birth. Upon examination the diaphragm was seen to block up the space between the vocal cords anteriorly, extending posteriorly for about one-third of the anteroposterior diameter of the larynx, where it ended in a sharp, indurated border. The clinical history of the second case was similar to that of the first; here, however, the diaphragm was more extensive, extending from the anterior angle of the vocal cords backward for about one-half of the anteroposterior diameter. Neither case showed any permanent improvement under treatment, although the attacks of laryngitis could be somewhat ameliorated.

Oxyuris Vermicularis as the Cause of Acute Appendicitis.—Rammstedt says that these intestinal parasites may occasionally be the cause of acute appendicitis, and reports a case in exemplification thereof. In the amputated appendix there was found a large mass of these worms, and the lesions of a catarrhal inflammation of the mucous membrane. No abscess was present. The appendix was bound to the cæcum by adhesions, so that it is evident that previous attacks had taken place. The total leucocyte count before the operation was 26,000, and it is interesting to note that such high figures do not, in all cases, signify the presence of pus. Cases of appendicitis due to intestinal parasites could, without doubt, be successfully treated with vermifuges and cathartics, but, since an accurate diagnosis of the cause of an appendicitis is impossible prior to the operation it is evident that it is not safe to delay the same, or substitute other treatment therefor.

Berliner klinische Wochenschrift, December 15, 1902.

Acute Inflammations of the Tonsil.—H. Beckman considers the acute inflammations of the tonsil as etiological factors in acute or chronic catarrhal conditions of the nares, pharynx, and middle ear. Extended observation has shown that in 95 per cent. of cases of the latter diseases acute tonsillitis, either directly or indirectly, is to be regarded as the cause. According to this conception, such acute or chronic inflammations can only be successfully treated by measures which shall directly combat the tonsillar condition. Much experience has shown that removal of the tonsils is the only safe course to be followed. The excision, however, must be complete, for if any of the tonsillar tissue is left behind the nasal and pharyngeal condition is but little, if any, improved. In twelve years the author has performed 9,000 such operations, nearly all of which were followed by a complete disappearance of the rhinitis, pharyngitis, or otitis.

Berliner klinische Wochenschrift, December 22, 1902.

Two Cases of Stramonium Poisoning.—Knaut reports two cases of stramonium poisoning which were caused by the ingestion of stramonium seeds. The patients were children, and had picked up the seeds while playing in the fields. The symptoms were intense, but were successfully combated by the administration of ipecac and apomorphia, although about two hours had elapsed between the ingestion of the poison and the administration of the emetics.

Chorea Electrica.—Ludwig Bruns considers under this name that peculiar nervous affection which was first described by Henoch and later by Bergeron. The disease occurs exclusively during childhood. The muscular twitchings are limited to the neck and shoulder muscles, and are electrical in character. That is, they appear as if produced by the passage through them of an electric current. The disease is in no way related to Sydenham's chorea. It may be divided into three varieties: (1) chorea electrica propria; (2) chorea electrica hysterica; and (3) chorea electrica epileptica. These varieties are, as a rule, easily differentiated, although at times the first two varieties may be confounded. As the name indicates, the second variety is hysterical in origin. It is easily cured by suitable treatment. which is of the same nature as that given to ordinary hysterical patients. The first and third varieties are very resistant to treatment. In the latter the attacks simulate, in many respects, true epilepsy.

Münchener medicinische Wochenschrift, December 23, 1902.

Cancroin "Adamkiewicz."—J. Decker has used inoculations of cancroin in four cases of carcinoma in which the diagnosis was absolutely assured. The number of inoculations given was 24. 16, 18, and 16 respectively. At each inoculation 1 gm. was given. In no case was any benefit whatsoever obtained, and it is very evident that the claims of Adamkiewicz for this preparation have been greatly exaggerated.

Parenchymatous Syphilitic Nephritis.—Max Wagner reviews the literature of syphilitic nephritis, and adds three more to the eleven which have hitherto been reported, and in which he regards the diagnosis as absolutely established. In all of these fourteen cases all possible sources of error in diagnosis were excluded. Furthermore, the action of mercury on the nephritis was specific in all, although in a few of them too large doses of this drug irritated the kidneys and temporarily increased the albumin and casts. For this reason care should be taken in the treatment of syphilitic nephritis by mercury. Small doses should at first be given, and in increasing the same the effect upon the urine should be carefully watched, and if the albumin and casts are not lessened, the dose should be at once reduced, and, if necessary, the administration entirely suspended for a time.

Perforation of the Nasal Septum among Workers in Chromate Factories.—J. Bamberger says that the perforation of the nasal septum so common among workers in chromate factories is due to the lodging of small particles of the chromate compounds on the septum in the location in which the perforation takes place. Experimentation with powdered magnesia has shown that the current of air entering the nostril first strikes the external wall of the same, and is then sharply deflected toward the septum, and that the largest portion of the magnesia which lodges in the nostril is not found upon the external wall, but on the septum. Thus the cause of the perforation of the sep-

tum by the inhalation of chromate compounds is readily explained. Those workers in such factories who suffer from nasal catarrh with abundant secretion very seldom suffer from the nasal perforation, because the secretion which covers the mucous membrane protects it from the action of the chromates.

French and Italian Journals.

The Histological Lesions in Cowpox.—M. E. Tabusso, during a severe epidemic of the disease in the Piemontese valleys, was able to make numerous researches into the nature of the disease. His conclusions are that, with the exception of a part of the pulmonary lesions, there are no specific lesions in cowpox, and that the anatomico-pathological findings are very similar to those of diphtheria and cholera in man, as well as those found in experimental yellow fever.—*La Riforma Medica*, December 13, 1902.

A Lesion Confined Exclusively to the Hepatic Endothelium, Due to Cocaine.—Gilbert and Carnot have observed in a rabbit, after slight, chronic intoxication by cocaine, a remarkable alteration of the liver, in that it affected only the endothelial cells. These cells were heavily loaded with fat, while the hepatic cells and biliary cells were healthy, and did not contain the least trace of fat. This interesting alteration indicates the considerable rôle that the endothelial cell plays in the antitoxic function of the liver in relation to dissolved substances, like cocaine, as well as in relation to insoluble substances, such as pigments, fat, or microorganisms. These observations show that there ought to be a place in the pathology of the liver for lesions of the hepatic endothelium. Under the influence of small doses of cocaine, the authors have obtained a fatty degeneration of the endothelium.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, December 21, 1902.

Treatment of Vesical Perforation by Transplantation.—L. Baldassati and R. Finotti have obtained excellent results by the use of a seromuscular transplantation instead of the epiploic transplantation usually employed. The muscular layer gives a strength of resistance which is better able to support the distensions to which the bladder is often subjected than is the epiploon. By its contact with the urine it protects the outer layer of peritoneum, and, moreover, it is of a thickness which causes it to adapt itself with exactitude to the portion of bladder wall to which it is sutured. The animals experimented on tolerated the operation well, there being merely slight and temporary disturbances. At autopsy it was found that the bladder was of normal shape and size, and presented adhesions to the omentum and sometimes to the intestines, so that the line of union with the transplantation could not always be perceived. At the point of operation the walls were thicker and more resistent, while the mucosa was normal in aspect, with only slight hollowing.—*La Riforma Medica*, December 18, 1902.

Torsion of Hydrosalpinx During Pregnancy.—According to Pinard, the first symptoms observed in this case were very grave, and suggested appendicitis; there were pains in the right iliac fossa, so intense that they caused nausea. But the localization of the pain was too low for this diagnosis to be maintained. Besides, the pain radiated to the right labium. Pulse and temperature were normal; there were no intestinal troubles, but there was frequent desire to urinate. Nephritic colic was thought of, and baths and morphine were prescribed. The condition remained stationary for several days, then vomiting of almost pure bile occurred, with severe diarrhœa, abdominal meteorism, and a very pronounced jaundice. The Pulse was 104. Manual dilatation was performed under chloroform, and the woman was delivered by forceps. The patient appeared to do well. But Pinard thought it wise to perform laparotomy. At the right of the uterus was a black tumor; it was a hæmatosalpinx, with twisted pedicle. The tube was removed. The unusual feature of the post-operative phenomena was the appearance of jaundice of great intensity.—*La Presse Médicale*. December 17, 1902.

Concerning Meat Diet. — Dufour placed four dogs on meat diet. In the beginning the animals took the meat in large quantities voluntarily—as much as 500 grams for dogs of six or seven kilos. Under its influence the following phenomena have been observed: Albumin appeared three times out of four in the proportion of .5 to .6 a liter; normal bile pigments were passed in the urine three times out of four, but urobilin was never determined. The quantity of indican became at least ten times greater than in the vegetable diet. The nitrogen coefficient was increased, but in spite of that the proportion of nitrogen not transformed into urea, and remaining in the state of products more or less toxic, became three or four times greater, a fact far more important than the absolute figure of the coefficient. All of the animals grew thin, the skin changed, and became the seat of generalized eczema, with disseminated ulcerations. Dufour concludes that the exclusive or excessive meat diet produces congestion of the kidneys and the liver, and increases notably the amount of toxic waste products of nutrition, which circulate in the tissues.—*Bulletin Général de Thérapeutique*, December 15, 1902.

Tuberculous Rheumatism.—Mouriquand describes a case of Poncet's. The patient was a boy who worked in a restaurant. He had a tuberculous family history. His mother died of the disease. A sister living is tuberculous. A cousin has tuberculous laryngitis. There is no history of gonorrhœa. From the age of twelve till he was twenty-two years he suffered with violent facial neuralgia, which occurred periodically every four or five days, and which was not relieved by quinine or antipyrin. In 1892 he suffered from an attack of true polyarticular rheumatism. His muscles were also affected. He spent one month in the hospital. In 1898 there were unmistakable signs of bacillary bronchitis. There was hæmoptysis. In March, 1902, he suffered from rheumatic pains in both thumbs. This resisted simple treatment. There was also intercostal neuralgia as well as laryngitis. In December, 1902, there developed rheumatism of both thumbs and of the radial sheaths. Both hands swelled. The apices of the lungs were affected. In the presence of rheumatic phenomena so pronounced, not relieved by salicylate of soda, and coincident with distinct lesions of the lung apices, Poncet has made the diagnosis of tuberculous rheumatism.—*Lyon Médical*, December 21, 1902.

The Journal of Medical Research, November, 1902.

A Study of Eel Serum, and the Production of an Antitoxin in a Cold-blooded Animal—A Contribution to the Study of Immunity.—Justin De Lisle concludes from his experimentation that eel serum is extremely poisonous when injected into the veins of the rabbit or guinea-pig. The immunization of the guinea-pig with eel serum has not yet been attained. That of the rabbit, although a delicate task, is usually successful. Inasmuch as the red globules of a rabbit vaccinated with the serum or the blood globules of an eel offer a higher degree of resistance to the dissolving action of eel serum than do the blood globules of the normal rabbit, and there is inability of the blood globules of the rabbit that has been vaccinated with the serum or the blood globules of the eel to neutralize the toxic principle in eel serum, together with the non-production of the sensibilizing body, the author concludes that eel blood, when injected into the organism of the rabbit, excites the red globules of that animal to produce an antitoxin.

Preliminary Note on Some Effects of Tobacco on the Tissues of Rabbits.—Isaac Adler describes a series of experiments conducted upon rabbits. The animals are fed exclusively on cabbage carefully mixed with an infusion of tobacco. A rabbit killed after two weeks of the treatment shows no signs of disease anywhere, even on the closest inspection. After two and a half months, an animal apparently in perfect health shows proliferation of the connective tissue of the liver; after four months there is progression of the same lesions. All other organs are, however, unaffected. This is as far as experiments have progressed up to the present, but the author presents this preliminary note at this early stage of experimentation because he considers one fact as reasonably certain—that is, that we have in tobacco infusion, administered as described, a toxic substance, probably one of many, which, acting with extreme chronicity, exerts its influence, at least in the earlier stages, exclusively upon the interstitial and fibrous tissue, uncomplicated by any parenchymatous degeneration or any gastric or intestinal lesion.

On the Erythrogenic Spleen of Mephitis Mephitica.—Walter R. Brinckerhoff says that in this animal the spleen shows evidence of active red corpuscle formation. The sections of bone marrow show a comparative paucity in cells of the erythrocyte series. Erythroblasts in all stages are present, but do not form a prominent feature of the section, as they do, for instance, in the normal marrow of the rabbit. In the pulp of the spleen all stages of red corpuscle formation are present. The erythroblasts lie in the sinuses in great numbers and form a prominent feature of the section. The fact that the spleen of M. Mephitica functions as an organ for red corpuscle formation is of interest on account of its bearing upon the problem of the loci of hæmatopoiesis. In this animal the spleen normally divides with the bone marrow the labor of erythrocyte production. In the majority of the higher mammals the spleen is more nearly related to the lymphatic system than to the bone marrow. In M. Mephitica the presence of erythogenic tissue, which is found only in the bone marrow of most of the mammalia, emphasizes the serial character of the three hematopoietic organs.

Society Reports.

THE PRACTITIONERS' SOCIETY,

176th Regular Meeting, Held on Friday, December 5, 1902.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

A Case of Pneumothorax.—Presented by Dr. W. GILMAN THOMPSON. The patient was a young man, twenty years of age, an Italian fruit vender, who was admitted to the Presbyterian Hospital ten days ago. He had never had any previous illness of any seriousness, and the only symptom of which he complained at the time of his admission was a cough, which had troubled him for two or three weeks. An examination of the patient's chest revealed a pronounced pneumothorax on the left side. The physical signs were typical of this condition, and upon aspirating the chest air was drawn off. There were no signs of pulmonary tuberculosis, but, after repeated examinations of the sputum, tubercle bacilli were found upon one occasion. The most interesting feature in connection with the case was the extreme displacement of the heart, which was crowded over to the right side fully as far as its natural position on the left side. In spite of the pneumothorax and the marked displacement of the heart, the patient, apparently, suffered no physical discomfort. There was no bulging of the chest wall, and very slight difference in the respiratory movements on the two sides of the chest. The heart sounds were normal. Dr. Thompson said that in a number of cases of pulmonary tuberculosis, treated by Dr. H. P. Loomis, in which he had seen nitrogen gas injected for the purpose of compressing the diseased lung, the gas produced a very rapid displacement of the heart, but the displacement was rarely so great as in this instance. For this reason, and because there was so little general disturbance, the question arose whether in this case the displacement of the heart might not be a congenital condition, and the pneumothorax merely a coincidence. The question also arose as to the advisability of aspirating the chest for the purpose of removing the air. That operation had been done a number of times. In 1900 such a case was reported in the *Transactions of the Presbyterian Hospital*, by Dr. Herbert W. Carter, who aspirated a simple pneumothorax, occurring in the service of Dr. W. P. Northrup. In that instance the patient suffered from pain and extreme dyspnœa, and the operation was done to equalize the pressure upon the affected side. Done under those conditions, the operation had always been successful, but in the case under discussion, there were apparently no indications for aspiration, and it was a question whether it would not be better to allow the lung to remain compressed for a time. The pneumothorax was probably the result of a minute perforation in a tuberculous area, and the compression of the lung served as a conservative process, acting in the same way as would an injection of nitrogen gas, by imposing rest upon the affected lung and allowing it to heal. The air in the chest, which was apparently causing the patient no discomfort, might eventually be absorbed.

Dr. BEVERLEY ROBINSON said he was inclined to agree with Dr. Thompson that it would be wiser not to aspirate the chest at present. By drawing off the air, a reopening of the perforation might result, and the tuberculous process might become more active. The marked displacement of the heart naturally gave rise to some apprehension, but, on the whole, he thought it best not to interfere.

Intracranial Neurectomy by a Simplified Method.—Presented by Dr ROBERT ABBE. The patient was a woman, forty years old. who had been operated on for inveterate tic douleureux only eight days ago. The method employed by Dr. Abbe was a modified intracranial neurectomy. Instead of the Hartley-Krause operation, with its large osteoplastic flap, Dr. Abbe made a vertical incision in the temporal region just within the hair line. He then chiseled a little hole through the thin portion of the temporal bone, and with the rongeurs gnawed away a section of bone about an inch and one-half in diameter. This was quickly and easily done, taking just ten minutes, while by the Hartley-Krause method it took fully twenty or twenty-five minutes to get through the bone. Dr. Abbe practically eliminated the danger of arterial hemorrhage in connection with the operation, by a preliminary ligation of the external carotid artery. In spite of this precaution, however, there would be a certain amount of venous oözing, and in controlling this, the speaker called attention to a little expedient that he had found of much practical value. Instead of trying to control the bleeding from the dura and bone by means of plugs of gauze, he used a narrow strip of sterile rubber tissue, wrapped over the end of a small wad of gauze. When this was pressed down upon the bleeding points, the blood instantly clotted, whereas gauze sucked up the blood and tore away the slow forming clot when it was removed.

Upon exposing the brain, instead of removing the Gasserian ganglion, as was now so widely advocated, Dr. Abbe dissected out the inferior and superior maxillary branches of the fifth nerve, and removed about half an inch of each on the inner side of the foramina rotundum and ovale. These two foramina of exit were then covered with a piece of rubber tissue, which was allowed to remain permanently. This interposed a non-conducting, sterile medium between the two nerve ends, and prevented them from reuniting. Recent investigations had shown that the regeneration of nerve cells took place very rapidly—usually within a month. If we could succeed in keeping the divided nerve ends apart for a longer period than this, a fibrous stump was formed which acted as a permanent barrier to the regenerative process, even if the rubber tissue were eventually absorbed, which, however, it was not. Dr. Abbe said that he had now done this modified operation seven times. In all of the cases the neuralgia was of the most inveterate type, and in all of them the relief was prompt and, thus far, permanent. The first case was operated on nearly seven years ago; the second, over five years ago; the third, three years ago; the fourth, eight months ago, and the rest more recently.

Before he undertook this modified method, Dr. Abbe said he had operated in a number of cases by the Hartley-Krause method. Those patients had also remained well, but the operation of removing the ganglion of Gasser was unquestionably a very severe one. There was danger of grave hemorrhage and shock, even in the best and most experienced hands; it took from one and one-half to two and one-half hours, and the speaker said he knew of one case in which it took four hours to control the hemorrhage. The operation he had described could be done within an hour. Dr. Abbe said that one advantage of the vertical incision which he resorted to in these cases was that it was not followed by any wasting of the tissues in the temporal region, such as was apt to occur after the usual horseshoe flap incision made in the Hartley-Krause operation. The interposed rubber tissue remained permanently in every case. He sterilized it by gentle rubbing with 1-1,000 bichloride solution before operation and immersing it in normal salt solution, from which it was taken and placed *in situ*. In a rabbit, he had removed a piece of rubber tissue placed upon the brain two years before by his assistant, Dr. W. S. Schley, and found the rubber intact and with only the slightest marginal adhesion on one side. Thus he disproved the statement that rubber might be disintegrated by time.

Dr. ROBERT F. WEIR said he was not convinced as to the ultimate value of the method described by Dr. Abbe. On the contrary, he was inclined to believe that any operation for the relief of intractable facial neuralgia which was limited to an attack upon the nerve on the distal side of the ganglion was a step in the wrong direction. Unless the ganglion was destroyed, the probability

of a recurrence must always be feared. In fact, the tendency was now to go even beyond the Gasserian ganglion, and the suggestion had been made to divide the sensory root and leave the ganglion alone. Dr. Weir said he agreed with Dr. Abbe that a transverse incision through the temporal muscle was apt to be followed by a disagreeable amount of atrophy. The severe hemorrhage incident to these operations was an important factor. Preliminary ligation of the common carotid had been suggested, but this was apt to lead to serious cerebral complications, as it took some time for a collateral circulation to be established. Instead of this, or instead of tying the external carotid, as practi ed by Dr. Abbe, the suggestion made by Dr. Crile of Cleveland was worthy of consideration. He advised and practi ed satisfactorily in animals and in the human subject the use of temporary pressure upon the common carotid with a rubber guarded screw clamp; this compression could be prolonged for an hour or two without causing any damage to the artery, and the patient received thereby all the benefits of a ligation. The interposition of various kinds of tissue between the divided ends of nerves or to prevent the formation of adhesions had been tried very extensively. Rubber tissue, gutta percha tissue, gold leaf, and sundry others that had been tried had been found to become perforated by granulations, and had thus lost their protective value. Used for the purpose described by Dr. Abbe, the rubber tissue might possibly act as a barrier between the severed ends of the nerves for a time, but the speaker said he would not like to rely too strongly upon its permanence.

The President, Dr. Joseph D. Bryant, said he had given considerable attention to this subject, and had endeavored to work out on the cadaver a method which would prove a little more feasible than that followed by Hartley and Krause. He was very favorably impressed with the vertical incision through the temporal muscles, as it was not followed by a subsequent impairment of the tissues in that region. This was well illustrated in the case shown by Dr. Abbe. So far as the interposition of rubber tissue between the divided ends of the nerve was concerned, Dr. Bryant said he was a little skeptical as to the permanent value of such a barrier. Still, there had been no recurrence in any of Dr. Abbe's cases, even in the one which was operated on over seven years ago, which would seem to indicate that the barrier had proven effective. After mere division of a nerve or the removal of a section, regeneration of the nerve was apt to be very prompt. The speaker said that in one case of facial neuralgia in which he removed one inch of the infra-maxillary nerve, the pain returned within three months. The patient subsequently died from another cause, and at autopsy a direct communication was found between the divided ends of the nerve. The method described by Dr. Abbe certainly opened up a field for careful investigation. Instead of removing a section of the nerve trunk beyond the foramen, as Dr. Abbe did, why would not a similar effect be produced by removing a section after its exit through the foramen, providing its ends were kept from reuniting? Should the method of practice employed by Dr. Abbe prove as beneficial as his results seemed to indicate, then, indeed, ought not, for various reasons, the surgical efforts to be directed more to the anterior than to the posterior parts of the nerves as later experience seemed to demand? On account of the severe hemorrhage and shock, the Hartley-Krause operation was a very formidable one, with an average death rate of about 8 per cent. Dr. Abbe, by the method he had described, had thus far no death rate.

Dr. Charles L. Dana said that the opinion now generally accepted by neurologists regarding the causation of tic douloureux was that the original trouble was due to a peripheral degenerative neuritis and arteritis, but that the degenerative process eventually involved the ganglion, and that a permanent cure could not be expected in old cases unless the ganglion itself were removed. The undoubted success of Dr. Abbe in cases he had reported was perhaps due to the fact that the operations were done comparatively early in the course of the disease; at least, before the ganglion had become much affected. Cases of facial neuralgia of recent origin—that is, if taken hold of within two or three years after the onset of the symptoms—could usually be quite successfully treated medically; but in the long-standing cases, the speaker thought, nothing short of complete removal of the ganglion would afford permanent relief.

Dr. Abbe, in closing, said that prior to treating these cases by this method, he had done the Hartley-Krause operation many times. He had also removed sections of the nerve trunks anterior to the skull, but this did not give satisfactory results. The procedure suggested by Horsely, namely, resecting the root of the nerve on the inner side of the Gasserian ganglion, had been tried by Horsley and Fraser in two cases, one of which was fatal. The operation was one of extreme gravity. Dr. Abbe said the feeling was growing upon him that cases of inveterate tic douleureux should at once be advised to have the intracranial operation done, instead of losing time in experimenting with the anterior methods.

Some Questions in Heredity.—Dr. Andrew H. Smith stated that he appreciated what the reader of the paper had said regarding the vagueness of the various forms of so-called heredity, and he did not know that we could establish any very positive data upon which to base an opinion as to the importance of this factor. The question of the soil being inherited and affording an opportunity for the development of certain morbid conditions was one which had recently been thoroughly ventilated, but it was an exceedingly complex subject, and Dr. Smith said he had never accumulated any special observations regarding it. As to the inheritance of longevity, he thought there could be no doubt about that. He could cite numerous instances among his acquaintances and patients in whose family records this tendency to attain advanced age was distinctly shown. In one particular instance that he had in mind, there were ten children in the family; four of these died rather early from acute disease, but the other six lived to an advanced age, the youngest being over seventy years and the oldest over ninety years at the time of death. The question of heredity possibly became complicated in a way he had never seen referred to in children who were the offspring of a woman during her second or subsequent marriage. Such a factor was well recognized in the breeding of lower animals. For example, a mare that had given birth to a mule, would, if covered by a horse afterward, give birth to a foal with certain asinine peculiarities, and those same peculiarities might be carried through several foals. He could not verify the assertion which he had heard made that a white woman who had given birth to a mulatto child would subsequently, and by a white husband, give birth to children who would show distinct Negro qualities. This entire subject of heredity was a very complex one, and could only be solved by an enormous accumulation of statistics. Our present impressions on the subject have been, no doubt, largely influenced by tuberculosis. Instances in which entire families, upon reaching a certain age, died of tuberculosis occurred to all of us, and they impressed us as examples of the influence of heredity, but even in those instances there was a disturbing factor. A careful investigation would generally show that the family lived in the same house from generation to generation, using the same furniture, etc. Particularly in country houses one room was usually set apart as a sick room; this was occupied by the successive members of the family when they were ill, and closed up when they died, generally without a disinfection, and thus the infection persisted. In cities, where the people were more apt to change their residence, the infection might be perpetuated by articles of furniture.

Dr. Robert Abbe said it seemed to him that the idea of hereditary disease—excepting, perhaps, in the case of syphilis—was assuming less and less prominence every

year. In cancer he had practically given up placing any reliance upon a family history of that malady. He had found very little satisfaction in tracing the history of cancer as an hereditary factor. He had practically reached the conclusion that the microbic diseases were not inherited (excepting, possibly syphilis), but that there were, undoubtedly, inherited tendencies. The latter fact he regarded as beyond dispute. Webbed-fingers, cross-eyes, and various physical defects were examples of this. We must admit that there were hereditary qualities, but not hereditary diseases. The greater or lesser vulnerability to disease must also be regarded as an hereditary quality.

Dr. Beverley Robinson said he had formed no absolute convictions as to the influence of heredity, but there was one phase of the subject which had not been touched upon, namely, individual habits which crop out at certain periods of life. These were apparently not influenced by environment, but developed in generation after generation, and they could only be explained, in his opinion, upon the theory of heredity.

Dr. W. Gilman Thompson said this subject had long interested him, and the question had often arisen in his mind whether heredity played any part in the production of the identical diseases to which Dr. Smith had referred in his paper. Heredity, in its broadest sense, was a conservative process for the preservation of the species, and, from a biological standpoint, it could hardly be expected that many diseases should be of an hereditary nature. Approached from a statistical standpoint, the theory of heredity was open to many fallacies, and all such figures should be considered in connection with the the laws of chance, as reduced to a mathematical science. If we took, for example, the statement that among ten thousand persons there were ten cases of carcinoma; five of these occurred in persons whose ancestors suffered from the same disease, and in the other five there was no such history. From those figures it would be quite as logical to argue that the disease was hereditary as that it was not. In weighing the value of statistics on this subject, therefore, a liberal margin should be left for the well-understood laws of chance. Dr. Thompson said he agreed with Dr. Abbe that heredity is regarded as a less important factor now than formerly in the very list of diseases which Dr. Smith mentioned. In gout, for instance, instead of the disease being inherited, it was the general habits of life, of diet, lack of exercise, etc., which acted as contributory factors. If the disease itself had been transmitted, its influence should become accumulative, and the disease factor strengthened in succeeding generations. Instead of this, the contrary could be shown in many instances in which the disease became extinct. The speaker said it was difficult to define what was meant by heredity, and too much importance had no doubt been attached to it. Alcoholism, for example, had been regarded as an hereditary and transmissible affection. It was probably the mental weakness, the lack of will power that was transmitted, and not often an actual, irresistible craving for alcoholic stimulants. This lack of will power was shown by alcoholic subjects in many other ways. In conclusion, Dr. Thompson said he was inclined to attach somewhat less importance to the influence of heredity in the transmission of certain diseases and specific dyscrasiæ than Dr. Smith.

Dr. Hermann M. Biggs said he did not regard tuberculosis in any of its varieties as an hereditary disease, in the proper sense of the term. There have been a few cases of tuberculosis found at birth—cases of intrauterine infection—but these were exceptional, and any type of tuberculosis developing after birth was no doubt the result of an infection occurring after birth. He constantly found a history of the patient's ancestors useful as throwing some light on the probable quality of the various types of tissues inherited, but that the diseases themselves were in any sense transmitted he had never believed. Different generations of the same family often showed a tendency to the development of cardiac disease, arteriosclerosis or renal disease, but this fact simply gave a suggestion as to the probable quality of these various forms of tissue. As regards alcoholism, he regarded it as an acquired taste and not a transmitted one, excepting in the sense that those persons had inherited a poorer quality of nerve tissue, and a lack of will power.

Dr. John Winters Brannan said he thought Dr. Smith, in his paper, had made a clear distinction between the possible inheritance of the disease and the inheritance of a lessened power of resistance. It was possible to conceive that the latter existed in certain families, especially in connection with certain maladies, such as renal or heart disease.

Dr. Virgil P. Gibney said he had long since satisfied himself that heredity played an unimportant part in bone tuberculosis. He was willing to admit, however, that there was a weakened resistance of the tissues in those cases. Even in club-foot, he did not regard the hereditary factor of much importance. Occasionally, it seemed as though these malformations were influenced by heredity, but, by going into the family history of a large number of those cases, the hereditary factor became less significant.

Dr. Charles L. Dana said he coincided in the opinion of the previous speakers that patients did not inherit diseases, but only constitutional defects. This distinction had been sharply drawn in neural pathology, and the name given to such a defective constitution was a "degenerative" constitution. In nervous diseases this showed itself in two ways: (1) Morphologically, where the inherited tissue died before its time. To this. Gowers had given the name of abiatrophy, which simply meant that in a person with, for example, Huntington's chorea, the cortical brain matter gradually died at an abnormally early age. In the same way, certain spinal affections, like hereditary ataxia, were the result of this premature decay of the nerve substance. These morphological tendencies, Dr. Dana said, were certainly strictly inherited, and might run through an entire family; they were called diseases, but were, more strictly speaking, teratological defects. The other form of defective constitution might be called physiological; it had not a distinct morphological basis, but simply meant that the brain and spinal tissues were born unstable and dynamically weak. A person with such degenerative defect might live to old age, but was apt to become the subject of various types of neuroses, epileptic attacks, forms of dementia, etc. It was on the above basis, the speaker thought, that the problems of heredity would eventually be solved, and they had been fairly well determined in connection with nervous diseases. As to how the diseases were actually acquired, he believed that in many instances this was accidental. It was known that locomotor ataxia was not inherited. Patients with that disease, as well as epileptics and paretics have had healthy children, who never developed any nervous disease. In regard to alcohol, Dr. Dana said he thought the craving for drink was a form of degeneration and mental weakness, which was inherited from parents or grandparents, who had defective constitutions. As a result of this inherited mental weakness, these persons were liable to various forms of psychoses. The drinking habit being so prevalent, the alcoholic psychosis was, naturally, very common. There were exceptional cases, however, in which the craving for drugs or alcohol was directly inherited, so that it showed itself in children during early life. In those instances, the children were born with a specific craving.

Dr. Alexander McPhedran of Toronto said he thought the term heredity was too widely used. Certain conditions could properly be spoken of as hereditary, while diseases could not. Tuberculosis could no more be regarded as hereditary than smallpox. Certain conditions and certain mental and physical states in children

usually followed the type obtaining in the parents. The term heredity should be restricted to such a tendency, and should not be applied to a disease with which the child became accidentally infected *in utero*. We were quite certain now that tuberculosis was an infective disease, and that children might be infected *in utero;* so also with syphilis and smallpox, and probably with scarlet fever and measles. If the term heredity was applied to a more restricted condition, it would, perhaps, be better understood. The accident of infection should not be classed with the inheritance of mental and physical peculiarities, which are, to a greater or less degree, constant.

Dr. William Mabon, discussing the subject from the standpoint of the neurologist, thought there were certain types of psychoses which were largely influenced by heredity, while upon other types it had little or no influence. He had seen some striking examples of the former type in some of the State institutions for the insane. In one instance a certain family had contributed a member or relative as an inmate of one of the various public institutions for fifty consecutive years. The fact must be recognized that many individuals whose parents have been insane would not of necessity become insane, excepting under peculiar stress. Such individuals had a lessened power of resistance, and when trials came they might break down under the increased burden. It was extremely difficult to secure any accurate statistics regarding previous cases of insanity in the patient's family. Many families were unwilling to disclose such facts in their history.

Dr. A. Alexander Smith, in closing, said that in no place in his paper had he taken the ground that a disease was distinctly inherited. He knew of no disease that could be regarded in that light. A disease with which a child was born was congenital, but not inherited. Tuberculosis and syphilis furnished examples of this type. He had, however, a very pronounced and emphatic feeling that heredity played a more important part in the development of certain diseases than the remarks of Drs. Abbe, Thompson, or Dana had conveyed to his mind. When they made the statement that it was some variation in the tissues that was inherited, they touched upon the important factor which he had endeavored to bring out in his paper, and wanted to emphasize now. With the possible exception of syphilis, we did not know of a single disease which was transmitted. Hamilton of Edinburgh had stated positively that syphilis could not be transmitted, while Jonathan Hutchinson claimed it could. Dr. Smith said he believed that heredity played an important part in the matter of the tissues, and the particular direction in which such hereditary influence showed itself developed a tendency to disease in that direction. The tendency to tuberculosis could only be called a tendency.

Death after Cerebral Embolism with a Ruptured Aneurysm of the Mitral Valve of the Heart.—Dr. Hermann M. Biggs showed a fresh specimen of a heart which had been removed from a man who had died suddenly several weeks after a cerebral embolism, the result, apparently, of a ruptured aneurysm of the mitral valve. There were two aneurysms on the aortic section of the mitral valve, one of which had ruptured. There were areas of extensive old and also a recent endocarditis affecting both the aortic and mitral curtains, and extending to the endocardium lining the left ventricle, covered with expansive vegetations. There were also isolated patches of disease in the aorta covered with vegetations and extensive thrombi in the auricular appendices. The heart was also interesting because of a very extensive defect in the auricular septum; the septum had two orifices, into each of which a finger could be readily introduced. The physical signs in this case had been limited to a loud basic murmur, which extended all over the upper portion of the chest and well up into the neck, and also a very loud systolic apex murmur, transmitted around the left side.

Gallstones.—Dr. Weir presented a specimen of a gall-bladder containing many small stones and a large one impacted in the cystic duct which he had removed without opening it, after having recognized through its thickened and somewhat distended walls several calculi and one particularly in the cystic duct, which could not be forced upward. The patient, a woman of thirty-eight, had had "cramping pains" at irregular intervals, but none so bad as the one which seized her four days before she was admitted to the Roosevelt Hospital. A painful tumor at the edge of the liver was recognized, though no fever or chills had been noticed. It was evident at the operation that a thickened and badly-inflamed gall-bladder co-existed with the cystic duct obstruction. No jaundice was or had been present, and her stools showed no alteration in color. Hence, instead of resorting to the usual procedure of first opening the gall-bladder and evacuating the contained calculi, which to a certain degree lends an increased risk from the probably infectious retained bile and secretions, the gall-bladder was quickly and easily separated from its liver bed, and with traction upon it the cystic duct beyond the obstructing gallstone was rendered readily accessible A double catgut ligature was passed around the duct, which was then divided, and the gall-bladder removed. An attempt was made to cover over the stump, but from its sinking deep into the wound this was difficult and was not persisted in. A rubber-and-gauze drain was then inserted. The gall-bladder, on being opened, showed not only thickening, but sloughing of its mucous membrane, and its fluid contents were decidedly purulent. Some forty or fifty calculi were found, and one, as large as the end of the finger, blocked up the cystic duct. The patient was doing well.

Dr. Weir then presented another set of gallstones, two of which, of rather large size, had been extracted, by a direct incision into the cystic duct for one of them and into the common duct for the other; the latter was some one and a half inches from the first cut, could not be forced through the original cut into the gall-duct. Several others, though smaller, were removed from the gall-bladder. The wounds in the ducts were left open, with drainage by a tube and gauze, down to, but not into, the duct. The gall-bladder itself was drained by a tube held in it by the inverted edges of the wound (the Kader principle). No jaundice existed in this case—only recurring attacks of pain. The stones, therefore, while caught, did not plug tightly the tube. It was an internal operation.

A third gall-bladder specimen was also shown by Dr. Weir, to illustrate a complication but recently recognized, and not yet recognized often enough to formulate the treatment. The gallstones presented were a dozen in number, and nearly of equal size, which was that of an average pea. The specimens had been removed from a woman of thirty-nine years, who had had several months ago a typical pain in the liver region, without jaundice. This recurred six weeks ago, with vomiting but no jaundice, and no change of color in the urine or stools. Three days prior to her admission to the Roosevelt Hospital another similar attack began, this time with jaundice. On her entrance into the hospital, this was already fading. On examination, there was no tumor nor decolored fæces or colored urine; no leucocytoses. The diagnosis made was escaping or escaped gallstones, with probable retention of others in the gall-bladder. On opening the shrunken and thickened gall-bladder, the few small stones were extracted, but palpation of the cystic and common duct failed to reveal any mass in them, but, on reaching the pancreatic region, a hard and large mass was felt, plainly due to a general increase in size of this part of the organ. Further examination to the left of the median line showed that the whole gland was increased in size and hardness, which, in some places was greater than in others. The query was at once raised whether this was neoplastic, or due to a chronic inflammation, perhaps to a

stone at present or previously impacted near the papilla of Vater, and allowing the entrance of bile into the pancreas. Nothing, however, could be felt to corroborate the latter view, and as the patient's condition, from the extra exploration which had been found necessary, was considerably deteriorated the wound was closed after a proper drainage had been inserted by Kader's inversion into the gall-bladder. A few days later, to test the patency of the common duct, some methylene blue was dropped through the drainage-tube into the gall-bladder, and, by its subsequent presence in the fæces, the patency of the gall-passage was established. Had this test, which Dr. Weir said had served him well in a number of instances, failed, it would have pointed toward a conviction of a blocking up of the pancreatic duct, and would have warranted a later opening of the duodenum, and the extraction of the obstruction. No evidence of pancreatic insufficiency had been found in the fæces. The patient was doing well, though no bile yet flowed from the drainage-tube in the gall-bladder.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 8, 1903.

HENRY HEIMAN, M.D., CHAIRMAN.

Vincent's Tonsillar Ulcer.—Dr. W. N. BERKELEY presented a child of six years having the Vincent tonsillar ulcer. Two nights ago the child complained of sore throat, and when first seen by the speaker yesterday there was slight fever, but no great constitutional disturbance. Examination showed a minute sloughing area over the upper margin of the right tonsil, about one-eighth of an inch in diameter. On pushing the slough aside with a swab, an excavated ulcer, about half an inch long, was revealed. Smears from it showed typical spirillæ, and the elongated bacilli described by Vincent. The precise relation of the bacilli to the spirillæ was not yet understood. As regards the treatment, nothing was necessary, except the use of antiseptic washes and liquid diet. Dr. J. Sobel, about one year ago, had described a series of these cases, and since that time a number of others had been reported.

Dr. CHARLES HERRMAN said that while there was no doubt about the diagnosis in this case these ulcers did not ordinarily present quite such a sharply defined margin, and were more of a greenish-brown color. The bacteriology of this disorder was still but little understood, and he thought in the future it would be shown that this form of ulceration occurred in other parts of the body than the throat.

Malnutrition with Small Heart.—Dr. SARA WELT-KAKELS presented a little girl showing malnutrition and anæmia. There was no history of syphilis, tuberculosis, or of nervous taint. This child was born at full term, but was a very small baby. She had always been thin and delicate, and appeared different from her sisters. Since last June various physicians had been consulted regarding her. Last September the child had been brought to her, suffering from severe and constant headache, lack of appetite, and constipation. Examination showed the child to be very much emaciated and pale, the complexion being almost greenish. Hypermetropia in both eyes was found, and was corrected by glasses, but this did not relieve the headache to any extent. The heart impulse could be felt in the fourth intercostal space, and the peripheral arteries appeared to be very small—so small that, in order to take the pulse, it was usually necessary to take it in the brachial artery. The child became cyanosed from time to time. One hour after a test-breakfast the contents of the stomach were examined, but nothing of great importance was found, except a deficiency in free hydrochloric acid. The daily quantity of urine varied between 350 and 500 c.c., instead of the normal quantity, 1,140 c.c. Microscopical examination of the centrifuged urine was negative. The quantity of urea excreted daily was 6.25 gms., instead of 18 gms. There was no sugar in the urine. Examination with the Gärtner tonometer showed the blood pressure to be only 69 mm., whereas normally it varied between 100 and 120 mm. The microscopical examination of the blood proved negative. Apparently, the condition was due to a hyperplasia of the blood vessels, or to a relatively small heart.

Dr. WELT-KAKELS then demonstrated the action of the Gärtner tonometer, the only convenient and satisfactory instrument at our command for taking the blood-pressure in clinical work.

Dr. HERRMAN said that these cases came under the group designated as infantilism. He now had such a case under observation, the patient being a boy.

Report of a Case of Paroxysmal Hæmoglobinuria.—Dr. CHARLES HERRMAN made this report. The subject of it was a boy of four years, born of apparently healthy parents. Very early in life the child developed unmistakable evidences of congenital syphilis, and was treated for this for about one year. On coming under observation, he was found to be rather undersized and anæmic. A hæmic murmur was heard in the neck. The heart and lungs were normal, and the spleen was not enlarged. Examination of the blood showed no malarial plasmodia. The attacks of hæmoglobinuria came on about ten o'clock in the morning, the child becoming, at this time, peevish, tired, and weak, and having a chill. Shortly after this a quantity of dark red, bloody urine would be voided. At first the attacks recurred at intervals of a few days, but there had now been no such attack for four weeks. On November 13 examination of the urine showed it to be brown in color, acid in reaction, and of a specific gravity of 1030. There was albumin. No red blood-corpuscles were found, on microscopical examination, but hæmin crystals could be obtained in the usual manner. According to the literature, only about twenty cases were on record, and there was a history of congenital syphilis in about one-half of the cases. The attacks could be produced artificially by cold baths, or by immersion of one extremity in cold water. Physical exertion and emotional shock were also causes. The theory was that hæmoglobinuria was preceded by hæmoglobinæmia. Dr. Herrman said he had examined the blood of this patient, applying various tests to it. The application of cold to the capillary tube containing the blood produced no change. An elastic ligature was placed around the index finger, and the hand and a portion of the forearm were placed in water at 45° F., for ten minutes. The part became cyanotic, and on the withdrawal of the blood coagulation took place in the usual way, and the serum was red, whereas it was yellow after the circulation had been restored. It was remarkable how this patient would recover so rapidly after apparently a severe attack; he would be playing around within an hour after the attack. When there was a history of syphilis, the administration of mercury and the iodides caused rapid improvement. The attacks were apt to recur in the winter, and continue for a number of years. In giving the prognosis, the possibility of the development of nephritis must be borne in mind. It was well to give the protoiodide of mercury for five days, and alternate this for a like period with peptonate of iron. The kidneys should be thoroughly flushed out by the free ingestion of water. When the attacks were frequent, the patient should be kept perfectly quiet, and during cold weather should remain in the house, and always be warmly clad. One observer had reported that he had been able to cut short the attack by the inhalation of the nitrite of amyl. The speaker suggested that a warm mustard bath would answer the same purpose.

Dr. L. E. LA FETRA said that during the past summer he had met with a case which might be called malarial hæmoglobinuria, yet it was not a pure case of this kind.

No plasmodia could be found in the blood, yet the administration of quinine increased the interval of the attacks, and prevented their recurrence for the past two months.

Dr. Henry Heiman said that the case reported was particularly interesting, because of the existence of syphilis of the kidney, as well as of the vascular system. An arteriosclerotic condition had probably been produced by the syphilitic virus.

Dr. Herrman said there must be some other factor than arteriosclerosis, because this was quite common, whereas paroxysmal hæmoglobinuria was exceedingly rare. The additional factor was probably a peculiar excitability of the vasomotor system.

Otitis Purulenta Neonatorum et Infantum.—Dr. Max Toeplitz presented a paper with this title. He said that in the infant the tympanic ring was much shorter than in the adult. The mastoid antrum and middle ear of the child were nearer the surface of the skull than later in life. The Eustachian tube in the child was wider, shorter, and more horizontal than in adult life. Prior to 1893 otitis purulenta of infants was considered an independent disease. In some cases the very high temperature and the presence of stupor or of convulsions suggested cerebral disease. A positive diagnosis of meningitis could only be made by lumbar puncture. Otoscopy in children was comparatively easy, but not so in the infant or new-born. The acute stage of otitis lasted from a few hours to a week or more, and terminated in spontaneous perforation, or in chronic otitis, or else in death from meningitis. The extension of inflammation took place through the mastoid-squamous fissure. In children primary inflammation of the labyrinth manifested itself by fever, convulsions, a tendency to vomiting, dulness of the sensorium, stiffness of the nape of the neck, and an irregular pulse. In children the patrous bones were rapidly destroyed. All the acute otitides were due to bacteria, chiefly the diplococcus pneumoniæ, the streptococcus pyogenes, and the staphylococcus pyogenes. These microorganisms usually entered through the Eustachian tube, by means of the nasal douche, or during sneezing or blowing the nose. The chief complications were facial paralysis, mastoid disease, brain abscess, and sinus thrombosis. Inflammations of the ear were twice as frequent in children as in adults.

After the diagnosis had been made, and this was not always easy, the child should be kept quietly in bed, given fluid nourishment, and the bowels should be thoroughly evacuated. Steam and hot water-bags were useful until it was evident that pus had accumulated, when paracentesis should be done at once, after having carefully sterilized the ear. The opening should be made in the posterior inferior quadrant of the drum, and the canal then closed with sterile gauze. Spontaneous perforation sometimes occurred, but it was always irregular, and was apt to leave irregular scars in healing, which interfered with the hearing later in life. As a rule, the discharge continued after both spontaneous and artificial opening of the drum. Under ordinary conditions it was best to employ the dry method of treatment, *i. e.* wiping off the secretions and dusting with a thin layer of some antiseptic powder, and then closing the canal with sterile cotton. This treatment was, however, only applicable when done under the supervision of the physician, or of a very intelligent attendant, and hence, in a large number of cases it was necessary to rely upon syringing.

Dr. E. Gruening said that in children one should very often look in vain either for a circumscribed bulging or a bulging of the whole drum of the ear in the presence of otitis. Inspection was more apt to show a general thickening of the epidermis and an obscuring of the usual land marks, and when this condition was present he would not hesitate to perform paracentesis of the drum. It was well in these cases always to examine both ears. He had seen quite a number of cases this winter, which had been complicated with bronchitis. It was almost wonderful how quickly the cough would subside after puncture of the ear drum. This fact seemed to point to the bronchitis being secondary to the otitis. It was impossible to make the external auditory canal aseptic; hence, the simplest method of treatment was by syringing. The use of a piston syringe required two hands; therefore, it was better to use a fountain syringe with the reservoir elevated only about six or eight inches above the head of the patient. In adults he preferred the dry treatment. As deaths had been reported, in which even by post-mortem examination nothing was revealed but the otitis media, the importance of prompt and efficient treatment was evident, and he would advise puncture of the ear drum when in doubt.

Dr. Carl Koller said that it had become evident in recent years that sinus thrombosis was comparatively common, and was the result of direct infection of the bulb of the jugular vein in the acute cases. Cases of pyæmia had been known to occur without any apparent thrombosis of the sinus.

Dr. E. Fridenberg said that it had been his lot to see a rather large number of middle-ear diseases in children which simulated other affections, and were consequently not recognized until the discharge from the ear occurred. These cases were not of the bronchial type, but were associated with gastroenteritis, or with intestinal catarrh. Some of the cases had been, at first, treated by their attending physicians for typhoid fever. In middle-ear suppuration in children one was apt to meet with great restlessness, or even with slight coma. He agreed entirely with Dr. Gruening as to the necessity of a free incision into the ear drum, in cases presenting severe symptoms, and evidence of accumulation of fluid behind the drum. The term "paracentesis" was unfortunate, because the old paracentesis needle was a very inefficient instrument, not giving a sufficiently large opening into the drum. The incision should be large and free—what might be called an internal Wilde's incision. He was not inclined to believe that any mechanical introduction of bacteria found in the nose or pharynx would ever produce a middle-ear disease, without the existence of a systemic condition predisposing to such disease. The intensity of middle-ear disease in children was explained by the anatomical conditions described in the paper, and also by the great thinness of the roof of the tympanic cavity.

Dr. Charles G. Kerley emphasized the importance, for those practising among children, of becoming familiar with the appearance of the normal ear. It was very awkward to make a diagnosis of pneumonia and then to find that the fever and urgent symptoms had most unexpectedly subsided on the appearance of a discharge from the ear. In his own experience these affections of the ear had been almost invariably associated with adenoids. He could not agree with the last speaker regarding the harmlessness of nasal douches, for he had known of one institution which made a practice of using saline irrigations of the nose and throat to keep its aurist quite busy until this practice was abandoned. He preferred making use of irrigations of 1 to 10,000 solution of bichloride of mercury every three hours at first, in cases of suppurative otitis.

Dr. Fridenberg explained that he, too, believed that irrigations, by inflicting traumatism, would cause otitis media, but, in his previous remarks, he had had in mind the use of the Politzer bag. His contention was that traumatism produced by the injection or irrigation was sufficient to produce otitis, irrespective of the question of the introduction of bacteria.

Dr. Toeplitz, in closing, said that he was in favor of using irrigations at first as often as every hour, the fluid having a temperature of 108° or 110° F. Baginsky made it a rule to examine the ears of all children coming to him, and he had found some affection of the ear in 80 per cent. of the children. Dr. Toeplitz said he had seen otitis purulenta

produced in very many instances after a douche or after bathing. This he explained on the theory that bacteria were carried in by the fluid. In performing paracentesis of the ear drum he made use of a knife of special shape, in order to insure a very free incision.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 10, 1903:

	Cases.	Deaths
Measles	120	6
Diphtheria and croup	344	46
Scarlet fever	206	11
Smallpox	1	..
Varicella	110	..
Tuberculosis	246	164
Typhoid fever	80	11
Cerebrospinal meningitis	..	..

GRATITUDE.

"Thank God for the doctor," the layman cried,
As he watched him with bated breath,
And saw the physician with skilful touch
Save the one that he loved from death.
"Thank God for the doctor," he humbly moaned.
"Every hour of my life I owe
To him who has saved us this life to-day;
Saved the home from its grief and woe."
There were honest tears in the layman's eyes
As he held, in a vise-like grip,
The doctor's hand that was thin and cold,
And pressed it with fervent lip.

. . . .

What a lovely thing is this gratitude!
How sweet the reward we gain!
For the labor we do for the sick and weak;
Our labor of hand and brain!
What a wealth we have for our daily work
For those who are sad and ill,
How sweet to the ear is the grateful word
Until we present the bill!
Oh, wise was the man who of Old Nick wrote
"When sick quite a monk he'd be,"
But gaining his health—what a truth it was—
That "devil a monk was he."

—Geo. Thos. Palmer.

Wonderful Old Men.—Men of thought have always been distinguished for their age. Solon, Sophacles, Pindar, Anacreon, and Xenophon were octogenarians; Kant, Buffon, Goethe, Fontenelle, and Newton were over eighty years; Michelo and Titian were eighty-nine and ninety-nine years respectively. Harvey, the discoverer of the circulation of blood, lived to be eighty years. Many men have done excellent work after they have passed eighty years. Landor wrote his "Imaginary Conversations" when eighty-five years old. Izaak Walton wielded a ready pen at ninety years. Hahnemann married at eighty years and was working at ninety-one years. Michel Angelo was still painting his giant canvases at eighty-nine years, and Titian, at ninety years, worked with the vigor of early years. Fontenelle was as light-hearted at ninety-eight as at forty years, and Newton, at eighty-three years worked as hard as he did in middle life. Cornaro was in far better health at ninety-five years than at thirty years, and as happy as a boy. At Hanover Dr. Du Boisy was still practising as a physician in 1897, going his daily rounds at the age of 103 years. William Reynold Salmon, M.R.S.S., of Conbridge, Glamorganshire, died on March 11, 1897, at the age of 106 years; at the time of his death he was the oldest known individual of indisputably authenticated age, the oldest physician, the oldest member of the Royal College of Surgeons, England, and the oldest Freemason in the world.—*Scientific American Supplement.*

Japanese Police and Rats.—The following account exemplifies the thorough manner in which Japanese officials carry out their orders: The *Drogisten Zeitung* says, last month the police of Kobe distributed to every house in town a package of arsenic, with directions for the use of the poison printed on each package, which latter was to be used in the destruction of rats, in accordance with the plan of the Department of Health in fighting the plague. A very prominent citizen of Kobe, and a political leader of some note, on the day after the distribution was made, called at the office of the Kobe *Chronicle* and lodged a complaint to the effect that he had been grossly insulted by the police. According to his account, a police officer on the foregoing day had walked into his dwelling, and without a word handed him a package marked "Arsenic." "What is that?" asked he. "That's for you," answered the officer. "For me?" inquired the astonished citizen, in whose mind, no doubt, visions of a hint to betake himself to the unknown shore after the "good, old" Japanese fashion, were floating. "Yes—for—you," repeated the policeman, pausing after each word to emphasize it. "The order has gone forth that all vermin shall die!" This was all that the astonished editor could get out of the wrathy politician, and the latter went away still raging against "the insult the police had put upon him."—*National Druggist.*

A German Ambulance Train.—Although it is impossible altogether to prevent railway accidents, it seems, at least, that some thing can be done to relieve the sufferings of those who have been injured. Both in America and in Germany ambulance trains are now in use, which are kept ever ready to be sent out for the purpose of affording speedy relief to the maimed.

The train, so far as its narrow limits permit, is as admirably equipped as any modern hospital; its operating room is fitted up with an operating table, with all the necessary appliances of antiseptic surgery. The ward of this hospital on wheels has eight removable beds, which can be used as litters, if need be. Reclining chairs complete the furniture of the ward. Every German railroad has a certain number of these ambulance trains, the road being divided into sections, and a train assigned to each. Trains are always side-tracked at a station, ready to be sent out. As soon as news of an accident is received, the water tanks are filled, and the railroad surgeons—who live in the vicinity of the stations—are called by telephone. Even the fast limited trains must give way to the surgeons, and are side-tracked, in order that the ambulance may speed to the scene of the accident. The admirable system which has been devised, renders it possible for the surgeons to reach the injured within half an hour after they have been informed of the accident.

Blood-sucking Mosquitos.—The habit of sucking blood is an acquired habit, confined to the female anopheles. The male insect will, at times, alight on a hand held perfectly immobile, and will probe about with his suctorial mouth, as if inclined to bite, but will invariably fail to do so. In a species of culex—culex elegans—the male is also a blood-sucker, and quite as voracious as its female. The female of a maculipennis will readily bite when enclosed in a test-tube, the open end of which is held in contact with the skin; but it is almost impossible to induce some culices to bite under such conditions. A pseudopictus, like the culices experimented upon, would not bite when enclosed in a glass tube. Anopheles of both sexes will readily suck up the juices of plants, and the females can be kept alive for several months by feeding them with sliced ripe fruit. The habit of sucking blood from a

vertebrate is not peculiar to mosquitos only, but is exhibited by various diptera. In some it is common to both sexes, but usually it is confined to the female, and may probably be connected with the development of the eggs.—Dr. Louis Sambon in *British Medical Journal.*

Temperature of 110° F. in an Infant Ten-Days Old.—C. W. Kahl reports the case of an infant of ten days whose temperature reached 110°, equal to 112° had the graduation extended as the mercury raised. It would be difficult to say how far the mercury would have risen had the author possessed a longer thermometer. There had been no action of the bowels in twenty-four hours. There was tympanites and every evidence of great pain. Cold baths were given every two hours, castor oil in 1 dr. doses was administered every four hours. Strychnia sulph., gr. ⅛; quinine sulph., gr. v; syr. simp., three ounces, was given in 1 drachm doses every two hours. The abdomen was rubbed with sweet oil and turpentine. On the next day the temperature was still as high, but the child rested better, and had a better appearance; there was no action from the bowels, although several doses of the oil had been administered, so magnesium sulphate was given every half hour and there was free action. At six P.M. of the same day the temperature was 99½°; the stools were at first hard and curded, followed by green and slimy stools. This condition lasted two days. The following day the temperature was 99°, the child nursed, slept well, the tympanites had disappeared. There was complete recovery.—*Pacific Medical Journal.*

Paroxysmal Tachycardia Associated with Epilepsy.—R. Travers Smith describes a case, the features of which he thus summarizes: (1) The patient inherited a predisposition to epilepsy. (2) The tachycardia commencing in early life, its sudden paroxysmal nature, its mysterious appearance, disappearance, and reappearance, its tendency to become more frequent and severe, are all suggestive of functional epilepsy. (3) The patient's vacant look in a paroxysm, the impairment of memory, occasionally amounting to unconsciousness, indicate a mild degree of the psychical disturbances of epilepsy. (4) The occurrence of polyuria after a paroxysm of the heart, as after epilepsy. (5) Minor epilepsy showing itself as well as the tachycardia, both occurring frequently, but without apparent order or sequence. (6) The subsequent appearance of major epilepsy in the same patient. (7) The decided improvement (if only for the time being) of the paroxysmal tachycardia on the administration of potassium bromide. (8) Perturbation of the heart's action has been observed as an aura in epilepsy.—*Medical Press and Circular.*

The Treatment of Acne Vulgaris.—George Henry Fox says that massage or pinching of the skin for a minute or two at a time will often give to a dry, barsh cheek a soft, smooth, and oily feeling. In a case of acne it quickens the cutaneous circulation, and hastens the absorption of nodules; it destroys all pustular lesions, whether superficial or deep seated; it tends to empty distended glands and obstructed sebaceous ducts, and gives life and tone to a skin whose inactivity is the prime cause of the disease in question. Many lengthy chapters and journal articles have been written on the therapeutics of acne. If the author were asked to give the practical treatment of the disease in the fewest possible words, he would simply recommend cold bathing, strict diet, systematic exercise, and the frequent use of the curette.—*The Medical Examiner and Practitioner.*

The High Value of Normal Saline Solution.—Even at the expense of reiteration, the value of normal salt solution in certain major conditions may be emphasized. Experience has abundantly shown that it is safe to employ hypodermically, and that its effect is prompt and more decided than possible to obtain by other means. Six drachms of sterilized salt dissolved in one gallon of sterilized water is the proportion which may be readily used, and this solution at a temperature of from 110° to 120° F. may be injected into the loose subcutaneous tissue in varying amounts and at varying intervals, according to the demands of the case. Normal salt solution is thus indicated in shock, hemorrhage, and in acute septic and toxic conditions.—*The Clinical Review.*

The Use of Spectacles in the British Army.—It seems, says the *Lancet*, October 25, that we are henceforth to become accustomed to what has hitherto been a rare sight in the army—many spectacled soldiers. From a paragraph in the *Army and Navy Gazette*, October 18, we learn that it has been proposed to issue spectacles to such soldiers of the British and native troops serving in India as may require them, to correct defects of vision. Medical officers have, our service contemporary understands, been called upon to report how many men will require glasses and the probable cost per annum involved thereby. Meantime, in order to carry out these instructions, the optical means of testing the vision of British and native soldiers in India will presumably have to be issued.

A Substitute for a Hair Pillow may be made by slipping a newspaper between the pillowcase and the feather pillow.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending January 10, 1903:

A CONTRIBUTION TO THE PATHOGENESIS OF THE URÆMIC STATE; THE PROBABILITY OF ITS PHYSICO-ELECTRIC SUBSTRATUM.

BY HEINRICH STERN, PH.D., M.D.,
NEW YORK.

ALTHOUGH it is universally understood that uræmia can only arise on the basis of renal insufficiency, there is a discrepancy of opinion as to the nature of its immediate causative factor or factors and to the mode of action of the retained metabolic substances.

Various excrementitious matters, such as carbamid, ammonia and its carbonate, creatin and creatinine, leucin, urochrom, pigmentary substances, and the potassium salts, alone or by their concerted operation, have been held responsible for the production of the uræmic state. The action of the retained substances is considered to be chemicotoxic by the vast majority of clinicians and investigators.

Abundant evidence, however, has been furnished that none of the retained, known products of metabolism are in themselves toxic to any degree. Ignoring for the present hypothetical toxalbumins and unidentified organic molecules, we find that the most pronounced poisonous qualities are yet divulged by the retained potassium salts. As a matter of fact, however, their quantity in the serum, even if complete anuria has prevailed for some time, is too insignificant to give rise to the grave manifestations which we designate as uræmic. Besides, the symptom-complex of potassium poisoning is not exactly alike to the one of uræmia, and, furthermore, there is no conclusive proof at all that the amount of potassium in the ash of uræmic blood is invariably increased.

Senator, in his work on renal diseases,[1] as regards the etiology of uræmia, occupies the same standpoint as did Meissner, Voit, Fleischer, and others before him, namely, that it is not the result of the retention of one specific urinary constituent, but of a number or of all such substances. Practically the same view is held by Bouchard,[2] according to whom uræmia is not the consequence of a single toxic principle, but the product of all those retentia which normally enter into the composition of urine.

Strauss,[3] the latest exponent of the chemicotoxic theory, who, after the example of v. Korányi,[4] tries to fix the origin of uræmia upon retained organic molecules derived from albumin disintegration, opines that his conception of the etiology of uræmia is more precise than that of Bouchard. With this I cannot concur, because he was neither able to describe the exact nature of these organic molecules, nor did he offer proof of their supposed specific toxicity; Bouchard and his followers, I think, stand upon a less hypothetic basis when they declare that we do not find in the blood of uræmia other factors than those exhibited in the normal state.

The physico-toxic theory of the causation of uræmia is based upon the frequently observed fact that there exists an augmentation of the molecular concentration of blood serum in uræmia, and upon the additional assumption that this higher concentration is due to accumulation of normal products of retrograde tissue-metamorphosis.

If there occurs no synchronous decline of the general metabolic processes, or if no, or but insufficient, vicariousness is displayed by other emunctories when the excretory activity of the kidneys, the organs paramount in depressing the osmotic tension of the blood, is diminished or totally suspended, the crystalloid substances rapidly accumulate in the serum, causing it to be hyperosmotic.

That most instances of uræmia are characterized by augmented molecular concentration of the blood serum is demonstrated by the determination of the latter's freezing-point. The freezing point of normal blood-sera lies between -0.55 and -0.57°C. A further depression of the freezing-point is indicative of the retention in the blood of abnormal amounts of soluble molecules. In nephritis *without uræmic manifestations* the mean freezing-point of the blood, calculated according to the findings of v. Korányi, Kossler, Lindemann, M. Senator, Rumpel, and Strauss, is situated between-0.58 and -0.59°. The average freezing points of the blood in various types of nephritis *with uræmia*, calculated from results obtained by aforementioned investigators and by Strubell and Kümmell, lie between -0.61 and -0.67°.

Lindemann,[5] who is of the opinion that the increased osmotic pressure of the blood is expressive of the prevailing disturbance in uræmia, was the first to maintain that most uræmic phenomena could be accounted for by the hyperosmotic condition of the blood.

I had given a somewhat similar interpretation to the various investigations some time before I heard of Lindemann's publication. My first communication upon this subject, entitled "Osmotic Pressure and Its Relation to Uræmic Manifestations,"[6] was, however, not read until the meeting of the American Medical Association at St. Paul, in June, 1901.

The phenomena occurring in the blood after injections of large amounts of concentrated salt solutions are the same as those in uræmia; they make their appearance together with the higher concentration of the blood when the elimination of the accumulated substances from the blood, on account of the resorptive qualities of the tissues, does not occur any longer.[7]

Novi[8] observed tonic and clonic convulsions in dogs after intravenous injection of a 10-per-cent. sodium chloride solution, in such amounts that the blood possessed twice its former molecular concentration, and he maintains that the origin of these convulsions is due to withdrawal of water from the cortex cerebri, a view, although expressed as early as 1887, practically concurs with the more recent teachings of osmosis.

In a rabbit, weighing 1,320 grams, I have observed convulsive phenomena after intravenous injection of 60 c.c. of a 15-per-cent. solution of NaCl. Cryoscopy showed $\vartheta = 0.72$, a marked depression from the normal.

The great number of molecules dissolved in the

plasma causing its hyperosmosis, tend to diffuse toward the less concentrated body liquids. During the uræmic state, the intercellular liquid in certain tissues may already possess a greater molecular concentration than the serum itself. Ultimately, all the fluids of the body present a similar degree of concentration.

The point of attack and the origin of the uræmic convulsive phenomena, according to the experiments of Landois[8], is situated without any doubt in the psychomotor centers of the cortex cerebri. This investigator, who found that extractive substances and salts applied upon the psychomotor centers of the cortex cerebri in dogs give rise to pronounced convulsive attacks resembling minutely the eclamptic or uræmic convulsions in men, maintains that the prodromic stage of uræmia is formed by the "continuous irritation" of some part of the nervous system by the crystalloids and other excrementitious material in the blood. He does not, however, account satisfactorily for the mode of production of the "continuous irritation," which, viewed in the light of osmology, may be an expression of the hyperosmotic condition of the blood and liquids in the brain.

Against this etiological conception of uræmia it could be maintained, as Strauss (*loc. cit.*), for instance, has done, that there are cases in which no analogy had been observed between the degree of molecular concentration and the intensity of the uræmic manifestations. While this contention is true enough, there are, on the other hand, very few instances of uræmia on record in which the freezing point of the serum was not depressed below -0.58°. Cases of chronic uræmia in which the freezing point of the blood serum was situated between -0.56 and -0.58°, that is, at the normal degree, are not only infrequent, but should be excluded from this consideration, for the reason that they are often spurious (many clinicians too readily designate as uræmic any and all nervous phenomena occurring during the course of chronic nephritis), and that the individual attacks are often very slight, which may be indicative of but little altered osmotic condition in the blood plasma or of a quickly passing hyperosmosis.

The not-existing parallelism between the degree of molecular concentration and the intensity of the uræmic process could be rather a question of personal equation, as in all other bodily conditions, than an exceptional or specific phenomenon. While hyperosmosis of the serum is the rule in uræmia, Korányi, and his followers consider it a concominant phenomenon and not its etiologic factor. Apart from the few instances in which uræmia had terminated lethally when Δ had been -0.57° and lower they draw attention to the fact that Δ had been found considerably depressed in a variety of disorders in which uræmia had not appeared. Looking, therefore, upon uræmia as a chemicotoxic process they assume that the specific poison consists of derivatives of perverse albumin catabolism; that is, of large almost insoluble or insoluble molecules, which, if at all, participate but very slightly in osmotic tension, and do not materially depress the freezing-point.

Among fourteen cases of uræmia following the chronic interstitial or the mixed form of nephritis which came under the observation of Strauss there were three, viz., one of mild, chronic uræmia, one of chronic and one of acute uræmia, in which the freezing points of the respective sera were normal. In the case of mild chronic uræmia the amount of retained nitrogen was about twice as large as in the normal; in the two other instances it was excessively increased. Although the more or less depressed freezing-points concurred with an increase of retained nitrogen, in the remaining eleven instances there appeared to be no parallelism between them. For instance, in a case in which Δ was -0.68°, the retained nitrogen amounted to 266 milligrams in 100 c.c., and in another in which Δ was found to be -0.69° the retained nitrogen amounted to 122 milligrams, that is, less than half of the former.

Furthermore, the promulgators of the theory according to which uræmia originates from the circulating derivatives of the albumin molecule, like the adherents of the physico-etiological theory, cannot demonstrate a direct parallelism between the substrate and the resulting phenomena; that is, in this instance, between the amounts of retention nitrogen and the severity of the uræmic manifestations.

Accepting, however, augmentation of retained nitrogen in uræmia as a proven fact, there is no evidence that an eventual serotoxicity is caused by accumulation of products of normal nitrogenous decomposition alone, or by such of altered albumin catabolism, or that its eventual poisonousness is of a purely chemical nature.

The albumin molecule is a complex molecule. Being soluble to a very slight degree only, if at all, it does not participate in depressing the freezing-points of the serum or other body liquids in which it is contained. On the contrary, the complex nitrogenous molecule not influencing osmotic tension of the liquid and representing the principal non-electrolyte of the blood-serum averts complete dissociation of the electrolytes and thereby further depression of the freezing point.

The non-electrolytes do not only interfere with dissociation; that is, they do not only limit the number of ions, but also retard their movement. The presence of non-electrolytes, therefore, disturbs and diminishes the conductivity of the electrolytes; that is, the electrical conductivity of the watery liquid in which they are contained.

In uræmia the large amount of retained nitrogenous material prevents dissociation of the total electrolytes, and reduces the electrical conductivity of the existing ions. In the concentrated serum of uræmia the excess of albuminous retentia increasing the friction of the ions diminishes or prevents their motility. The proportion of non-dissociated, neutral molecules to the active, the ions is excessively large. While the ions as independent molecules participate in increasing osmotic pressure and in depressing the freezing point, the excessive high osmotic tension of uræmic serum is not due to its ions, but to its contents of neutral molecules. The ions alone, in the number in which they usually occur in uræmic serum, would neither increase its osmotic condition to any extent, nor would they materially depress its freezing point.

Determination of the freezing point of uræmic blood discloses therefore but one fact, namely, that of its high molecular concentration, its hyperosmosis, it does not reveal the presence of excessive amounts of nitrogenous substances, nor is the freezing point of the serum, *per se*, an indicator of its degree of electrical conductivity.

Dissociation of electrolyte molecules into ions occurs in the ratio of the dilution of the watery solution. The larger the amount of water the more readily ensues this process, the greater the proportionate number of ions and the electrical conductivity. Molecular conductivity is entirely independent of molecular concentration. The greater the amount of the dissolving agent within a certain limit, the greater the conductive properties of a given amount of electrolytes.

In acute uræmia, when complete anuria prevails, the dissolving agent occurs in larger absolute amounts; relatively, however—that is, in proportion to the total retained excrementitious substances, it is not increased.

The conductivity of human blood serum increases with its dilution. In other words, the more concentrated the serum the less its conductive qualities. Uræmic serum consequently displays a low degree of electrical conductivity.

Viola[10] investigating the relation of serum dilution to serum conductivity found the following:

DILUTION.	PHYSIOLOGICAL CONDUCTIVITY (in reciprocal Ohms).
Undiluted Serum	111.8
1 Serum + 1 Water	125.61
1 " + 3 "	141.76
1 " + 7 "	151.06
1 " + 15 "	154.02
1 " + 31 "	162.62
1 " + 63 "	160.98
1 " + 127 "	164.26
1 " + 255 "	158.41
1 " + 511 "	152.57
1 " + 123 "	130.56

The principal non-electrolytes of the blood serum are the albumin substances and their derivatives, of which it contains about 7 per cent.; all other non-conductors, such as glucose, lecithin, cholerestin, etc., occur in too insignificant quantities to interfere materially with the conductivity of the serum. During the uræmic state, the nitrogenous products of catabolism in the serum are found to be greatly augmented; the other non-electrolytes are never found increased to such a degree as the albumin derivatives are. In coma diabeticum, on the other hand, it is likely that the hyperglycæmic condition stands at the foundation of a diminished electrical conductivity of the serum.

Bugarszky and Tangl[11] found that the addition of 1 per cent. albumin to the blood serum caused an average diminution of 2.5 per cent. of the latter's electric conductivity. (They also demonstrated that about 7 per cent. of the serum electrolytes consisted of NaCl, that Na_2HP_4O does not exceed 3 per cent. and that the remainder consists almost entirely of Na_2CO_3. Thus it evinces that the electrolytes of the blood serum are mostly inorganic salts; the organic salts occur in such small and varying amounts that, normally, they do neither diminish nor augment the electrical conductivity of the serum to any extent.)

The experiments of Bugarszky and Tangl leave no doubt that the albumin molecule diminishes the physiological conductivity of the blood serum; being acquainted with the fact that addition of carbamid, for instance, to a solution of NaCl prevents the latter s complete dissociation, we may go a step further and assume that all the complex organic molecules retained in the blood serum occasion its diminished state of electrical conductivity.

Diminished electrical conductivity of the serum seems to be the direct etiological substratum of the uræmic attack; the lowest conductivity of human blood yet found, 98.29, was demonstrated in the serum of a case of uræmia gravis cum coma (Viola, *loc. cit.*). In healthy individuals the same observer found the conductivity of the serum between the extremes 106.18 and 119.*

Infusion of water, or under certain conditions, of artificial serum, with or without preceding abstraction of blood, dilutes the serum in such a manner that it may exhibit greater conductive properties. This therapeutic evidence of the reduced conductivity of uræmic serum is obtained in a certain proportion of cases only, preeminently in such on the basis of parenchymatous nephritis. In others, therapeutic measures avail nothing whatsoever. A number of reasons may be assigned for this, viz., dilution of the serum may not have been sufficient; albuminous retentia may have been present in too large a quantity; normal electric conductivity may have been suspended for too long a period, or secondary changes may have taken place. As a general rule, the less retention nitrogen in the serum the greater the chances of reestablishing its normal conductivity by dilution, that is, by enhancing dissociation of the retained molecules. Thus, it seems the uræmic phenomena in parenchymatous nephritis can be more readily and frequently subdued than in the interstitial form; one reason, and probably the most formidable, for this is, that in the former the retained nitrogen never or hardly ever exists in the enormous amounts in which it is found in the interstitial type.

The occurrence of greater amounts of retention nitrogen in the serum of uræmia on the basis of interstitial nephritis will, in a measure, explain its greater "virulence." While the retained nitrogen without any doubt reduces the physico-electric qualities of the serum, and while the co-ordinate and successive manifestations commonly designated as uræmic may be accounted for by the diminution or partial suspension of electrical conductivity in the serum, the accumulated albumin derivatives possibly call forth a secondary intoxication, which may be particularly noticeable when certain uræmic sera are intravenously injected into animals. This procedure, however, does not absolutely demonstrate the chemicotoxicity of the uræmic blood in the organism whence it is derived. Manipulation of of the blood, and may it be conducted under ever so many precautions, always changes its physical condition, and is never without influence upon its chemical nature. Diminished conductivity of the serum is such an inevitable and potent factor in the production of uræmic phenomena, that its importance overshadows the eventual occurrence of a secondary toxicosis.

An additional fact was pointed out by Bugarszky and Tangl, namely, that temperature elevation of 1° C, causes an increase of 2.21 per cent. in serum conductivity. Recalling that in most instances of uræmia, especially in those accompanied by deep and prolonged coma, the body temperature is considerably lowered, we understand again that diminished conductivity of the blood serum stands at the foundation of the uræmic syndrome. The influence of temperature upon the degree of electrical conductivity, however, is not only observed in pathological states like urænia, but in all phases and conditions of protoplasmatic life. With few exceptions, the higher the temperature the greater the dissociation of electrolytes, the greater again the chemical activity and the evolvement of heat, but if beyond a certain degree the greater the danger for the continuance of the life of the organism. The lower the intraorganic temperature the smaller, as a rule, the dissociation of electrolytes, the slower the vital processes. A temperature below a certain degree is inimical to the maintenance or production of a proper conductivity of the fluids of the protoplast or total organism, and consequently to the continuance of vital functions.

Recapitulating the principal points dwelled upon

*Viola mentions also a case of "chronic nephritis with uræmia" in which the conductivity of the serum amounted to 125.19. It is not stated whether uræmia in this instance was of a chronic nature, which seems most likely. As he designated the other case as "uræmia gravis cum coma," we may conclude that in the instance of chronic nephritis with uræmia the uræmic phenomena were of a mild character.

and derived at in the foregoing, it is made evident that the uræmic state arises on the foundation of diminished electrical conductivity of the serum, or at least, that insufficient serum conductivity is a potent contributing factor toward its production.

1. None of the retained known products of metabolism are in themselves toxic to any degree.

2. In uræmia there is a higher molecular concentration of the blood serum, which is due to the accumulation of normal products of catabolism.

3. Hyperosmosis of uræmic serum is evidenced by determination of its freezing point. The freezing points of normal blood sera lie between -0.55 and -0.57° C., those of uræmic blood sera are depressed to between -0.61 and -0.67° C.

4. The point of attack and the origin of the uræmic convulsive phenomena is situated in the phsychomotor centers of the cortex cerebri; the hyperosmotic condition of the blood and liquids in the brain may occasionally furnish the stimulus to the uræmic attack, but there is no analogy between the degree of molecular concentration and the intensity of the uræmic process.

5. In uræmic serum there occurs invariably an abnormally large amount of retained nitrogen. There is no parallelism between the degree of freezing point depression and the amount of retained nitrogen.

6. Non-electrolytes do not only interfere with complete dissociation, that is ionization, but also retard ionic movement. Their presence, therefore, lessens the electrical conductivity of the watery liquid in which the electrolytes are contained.

7. In uræmia the large amounts of retained albuminous derivatives exhibit most potent non-electrolytic qualities.

8. The ions as independent molecules participate in augmenting osmotic tension and in depressing the freezing point; the excessive high osmotic pressure of uræmic serum is not due to its ions, but to its contents of neutral molecules.

9. Determination of the freezing point of uræmic serum discloses the fact of its high molecular concentration, but not the degree of its electrical conductivity.

10. Dissociation of electrolyte molecules into ions occurs in the ratio of the dilution of the watery solution. The more concentrated the serum the smaller its conductive qualities.

11. The conductivity of the blood serum of healthy individuals varies between 106.18 and 119.12. The lowest conductivity of human blood yet found, 98.29, occurred in a case of uræmia.

12. Intravenous injection of water for therapeutic purposes dilutes uræmic serum in such a manner that it may exhibit greater conductive properties.

13. Normal conductivity of the serum is more readily and frequently re-established if the uræmic state has developed on the basis of parenchymatous nephritis than if it occurs as the consequence of interstitial nephritis. A most potent reason for this is the fact of the existence of smaller amounts of retained nitrogen in the parenchymatous than in the interstitial type of the affection.

14. In most instances of uræmia, especially in those characterized by deep and prolonged coma, the body temperature is considerably lowered. This fact again contributes toward reduction of serum conductivity. Elevation of temperature, on the other hand, as long as within well-defined limits, tends to increase the conductivity.

REASONS FOR BELIEVING THAT THE ONLY WAY IN NATURE* FOR YELLOW FEVER TO BE CONTRACTED BY MAN IS FROM THE MOSQUITO.†

By JOHN W. ROSS, M.D.,
SURGEON U. S. NAVY.

This article is intended mainly for the busy medical man, who, from want of time and lack of opportunity has not kept up with the details of the remarkable revolution which has taken place during the last few years, in our knowledge of the etiology and prevention of yellow fever.

Havana, the chief focus and home of yellow fever, was constantly afflicted by that disease, never a month without deaths from it, from 1762 to September, 1901, a period of about 140 years. Eight months subsequent to the beginning of the American antimosquito sanitary work, which was based entirely upon the mosquito idea of the propagation of that disease, yellow fever had disappeared altogether from Havana, and since, up to the present time—an interval of fourteen months, embracing two autumns and a summer—not a single case of the disease has occurred in that city. The intervening summer was an unusually hot one, and the city contained an unusually large number (at least 40,000) of recently-arrived non-immunes—just the conditions, which under the former régime must inevitably have produced a severe epidemic of yellow fever.

Sanarelli's proposed solution of the yellow-fever problem, of which we had such high hopes four or five years ago, has been proven untenable by numerous high authorities and skilled investigators. The United States Army Yellow-Fever Commission, composed of Major Walter Reed and Doctors Carroll, Lazear, and Agramonte, United States Army, which visited Havana first in the early summer of 1900, investigated its claims and found that:

"1. The Bacillus icteroides, Saranelli, stands in no causative relation to yellow fever, but when present should be considered as a secondary invader in this disease.

"2. The mosquito serves as the intermediate host for the parasite of yellow fever."

This commission returned to the United States the same summer, two of its brave members having had yellow fever, from which one of them, Dr. Jesse W. Lazear, died, thereby adding one more noble

*Yellow fever can with great certainty be produced by inoculating non-immunes with blood taken from persons affected with that disease; but, for obvious reasons, this cannot be called a natural method.

†Read before the American Public Health Association, New Orleans, La., December 10, 1902.

name to the long roll of medical martyrs who have yielded up their lives trying to help their fellow-men.

The latest utterance I have read about the Bacillus icteroides, that of Dr. Porthier, a member of the recent "United States Public Health and Marine-Hospital Commission on the Investigation of the Yellow Fever and Mosquitos in Vera Cruz," is, in part, as follows:

"The Bacillus sanarelli was doomed. The work of Reed and Carroll as to the transmission of yellow fever by the *Stegomyia fasciata* has been entirely corroborated." (*Journal of the American Medical Association*, November 8, 1902, p. 1207).

In 1881 Dr. Charles J. Finlay, a scholarly scientist, a British subject, born in Cuba, and a resident of Havana, promulgated the theory (now an established fact) of the transmission of yellow fever by the mosquito, and singled out the guilty species, now called *Stegomyia fasciata*. For many years subsequently he conducted experiments and published numerous articles attempting to convince the medical profession of the correctness of his views. In one of his contributions, read at Buda-Pesth in 1894, he recommends the following measures against the propagation of yellow fever through mosquitos, which, from our present point of view we may call prophetic:

"1. To prevent those insects from stinging yellow-fever patients.

"2. To destroy, as far as possible, the mosquitos which have been infected.

"3. Finally, to consider any place unsafe so long as the last mosquitos which have stung yellow-fever patients may be alive in it."

The beginning of this philosophic work of Finlay antedated by two or three years any of the mosquito-malarial theories and demonstrations. It occurred about the same time (but altogether independently) as the discovery by Sir Patrick Manson of the transmission of the *filaria nocturna*—the worm which causes elephantiasis Arabum—by mosquitos.

The brilliant work of Ronald Ross—1895-1899—Grassi, Marchiafava, Celli, and others, especially that of the first-named scientist, establishing the cognate fact of the conveyance of malaria by the anopheles mosquito, had great influence in leading to the demonstration of the transmission of yellow fever by mosquitos.

The clear-cut, scientific observations and classical contributions of Surgeon H. R. Carter, U. S. Marine Hospital Service, showing the interval (about two weeks) which occurs in houses between the first (infecting) case and the first group of cases secondarily infected; so interesting and impossible to explain by the fomites theory, are now readily understood in the light of our present knowledge of the elaboration of the yellow-fever poison in the body of the mosquito—that process requiring not less than twelve days.

The Army Medical Commission, presided over by Walter Reed, First Vice-President of this association for the present year, whose recent untimely death—an incalculable loss to the medical profession and to humanity—we are now mourning, returned to Cuba in the autumn of 1900, and resumed their mosquito-yellow-fever investigations. The reasons given by Major Reed for taking up the mosquito problem were:

"1. Finding that Sanarelli's bacillus had nothing to do with the causation of yellow fever.

"2. The unsatisfactoriness of the proof of the propagation of the disease by fomites.

"3. The perfect demonstration by Ronald Ross, and the Italian observers, that the anopheles mosquito is the intermediate host and conveyer to man of the malaria parasite.

"4. Carter's establishment, published in May, 1900, of the two to three weeks' interval between the first (infecting) case of yellow fever in a house or ship and the subsequent outbreak or group of cases."

This commission's subsequent work continued during the remainder of the autumn, and following winter, 1900-1901.

They produced thirteen cases of yellow fever by having non-immunes stung by contaminated mosquitos (*Stegomyia fasciata*). Three other cases were produced by direct inoculations of the blood of yellow-fever patients.

These experiments were conducted in such a manner as to make it impossible for the patients to have contracted the disease in any other way. Each case was diagnosed positively as yellow fever by the official yellow fever commission of Havana, composed of such eminent experts as Finlay, Gorgas, Guitéras, and Albertini. The function of this commission was to make diagnosis of all cases reported as suspicious of being yellow fever.

The famous paper read by Major Walter Reed before the Pan-American Medical Congress, Havana, February, 1901, describes his flawless procedures which leave no possible room for doubt that yellow fever is contracted by man from the mosquito. Nevertheless, the medical profession of Havana remained unconvinced, and similar experiments, with similar results, were repeated during the succeeding year inside the city of Havana, at Las Animas Hospital, of which I was at the time the director. An "Inoculation Station" was established in that hospital, under the immediate charge of Dr. John Guitéras. Eight experimental cases were then produced at Las Animas. The diagnoses were verified by the Yellow Fever Commission of Havana. During their illness the patients were unrestrictedly visited by the leading physicians of Havana.

Thus, it will be seen that twenty-one well-marked cases of yellow fever—Reed's thirteen and Guitéras's eight—representing the different varieties and intensities of the disease, were unquestionably caused by the bite of contaminated mosquitos, within the established incubation period (one to six days), with almost mathematical precision. Three of these mosquito-borne cases proved fatal, and the necropsy revealed the characteristic lesions of yellow fever. The demonstration of the fact that yellow fever is produced by the mosquito was then, for the first time, accepted as complete by the physicians of Havana.

It now remains to consider whether or not yellow fever is capable of being produced in nature in any other way. This question is so important, and doubt in regard to it so natural, that I shall give in detail two sets of experiments—one (1) conducted for its elucidation at Quemados, by the United States Army Commission, the other (2), at Las Animas Hospital, by myself. In these two sets of experiments every possible effort was made to cause yellow fever by fomites, the result in each instance being a signal failure:

"1. There was erected at Camp Lazear (one mile from Quemados, and about seven miles from Havana) a small frame house with a cubic capacity of about 2,800 feet, tightly ceiled and battened, provided with small windows, so as to prevent a thorough circulation of air through the house, and with wooden shutters to prevent the disinfecting qualities of sunlight. The windows were closed by permanent wire screens with a 5 mm. mesh. The

vestibule was protected by a solid door and a wire screen door, and the inner entrance by a second wire screen door. In this way the passage of mosquitos into the room was effectually excluded. The average temperature was kept at 76.2° F. for a period of sixty-three days, and precaution was taken to maintain sufficient humidity of the atmosphere. On November 30 three large boxes filled with sheets, pillow-slips, blankets, and so on, contaminated by contact with cases of yellow fever and their discharges, were received and placed in the room. Most of these articles had been taken from the beds of patients sick with yellow fever in Havana. Many of them had been purposely soiled with the excretions of patients. These soiled sheets, pillow cases, and blankets were used in preparing the beds in which the members of the hospital corps slept. During sixty-three days this building, thus furnished, was occupied by seven non-immune persons. Three of them occupied the room each night for twenty days. Later, a fourth box of clothing and bedding was added, some of it purposely soiled with the bloody stools of a fatal case of yellow fever. Two of them occupied beds from December 21 to January 10, every night wearing the very garments worn by yellow-fever patients throughout their entire attacks, making use exclusively of their much-soiled pillow-slips, sheets, and blankets. At the end of twenty-one nights they went into quarantine (as had the former three) and were released five days later. Two other non-immunes occupied the same beds for twenty days more. The attempt, therefore, which was made to infect this building and its seven non-immune occupants during a period of sixty-three days was an absolute failure; all seven were released from quarantine in excellent health."

Later on some of these same men were bitten by yellow-fever mosquitos, and promptly came down with yellow fever.

These fomites experiments have been pronounced inconclusive by many medical men upon the grounds, chiefly, that they were conducted during the winter season, and in the country, outside the city.

The following extract from my "Report of Experiments with Yellow-Fever Fomites at Las Animas Hospital, Havana, Cuba, September-November, 1901," read before the International Sanitary Congress, Havana, February 10, 1902, sets forth the principal details and results of the second set of experiments, in which the objections urged to the first set are removed.

"2. Two rooms were selected in buildings constructed of masonry, about 150 meters apart, both within the hospital enclosure. These rooms were thoroughly renovated, provided with doors and windows of wire gauze—mosquito proof—being further protected by vestibules of the same material. All the cracks and rough places in the walls, ceilings, and floors were smoothly sealed; and an abundance of pyrethrum powder burned in the rooms, in order to preclude the possibility of the presence of any mosquitos. One of these rooms was called the observation room, and the other the experimental room.

"The observation room was fitted out with furniture, utensils, bedding, and clothing, which had been thoroughly disinfected, so that there could be no suspicion of extraneous contamination.

"In the experimental room were placed numerous bundles containing clothing, bed clothes, and bedding, which had recently been used in the sick rooms and on the persons of patients ill with yellow fever; much of it badly soiled with discharges and excreta of said patients. These articles had been used by Venturo Trillo Ramos and Juan Lago, at the private hospital La Benefica, Havana (usually an infected place), and by patients in the hospital at Columbia Barracks, Quemados, Cuba. All these cases had been diagnosed as yellow fever in their respective hospitals, and confirmed as such by the Yellow Fever Commission of Havana. The cases of Juan Lago and Vicente Real were fatal, the latter having presented, during its course and at the autopsy unmistakable appearances of malignant yellow fever.

"Eight men, newly arrived on the island, five Spanish, two Italian, and one English, all healthy, by no possibility immune, were procured from the immigration station, Triscornia, across the bay from Havana, as subjects for our experimentation.

"Two of these men were placed in the observation room on September 27, and confined there for more than a week. At the end of that period they were transferred to the experimental room, where they were kept for seven days. They were then released and given light work in the hospital grounds. When they were removed from the observation room, two others of the subjects were placed therein for seven days—afterward taking their turn in the experimental room for the same length of time. In this way, all eight of the men, after rigid physical examination, went through the observation and experimental rooms, two by two, emerging thereform in good health, and remaining so until all possibility of having contracted yellow fever had passed away.

"While in the experimental room the subjects used, upon their persons for sleeping, the night shirts, pajamas, bedding, bed-clothes, etc., above described, soiled with fecal dejections, black vomit, and blood. From time to time other packages, containing similarly soiled fomites, were introduced, and the subjects required to shake them frequently within the room. While in the observation room, the men were not allowed to leave it, except for necessary exercise, and then under guard. While in the experimental room, they were not allowed outside under any condition. Their food was carried to them, and there were guards over them night and day.

"A careful clinical record was kept of each man during the fourteen days he was kept in the observation and experimental room. The temperature, pulse, respiration, appetite, etc., of all eight continued practically normal throughout.

"At the beginning of these proceedings written invitations were sent to the physicians of Havana, requesting them to visit Las Animas at their pleasure to observe the progress of the experiments.

"I beg leave to call especial attention to the following facts in connection with those experiments, viz.:

"1. They were conducted in the city of Havana itself, within whose beautiful limits, until recently, Cuba's yellow sorrow had run riot continuously for 139 years.

"2. They were conducted in buildings, similar in construction and material (mamposteria) to those occupied by people of the poorer classes of the city—damp, poorly lighted, badly ventilated, floors on the level of the ground.

"3. They were conducted at the season of the year when, in this latitude, the dreaded scourge is at its worst, and does its most deadly work. Said period comprising the latter part of September, the whole of October, and the first part of November—the height of the yellow fever season at Havana.

"Military-Governor Wood, with his characterisically clear perception, appreciated, from its very beginning, the promise and importance of the mosquito-yellow-fever work in Havana. He gen-

erously provided the funds for the experiments and for the large expenditures, sometimes $35,000 a month, subsequently and consequently required by Major Gorgas, the Chief Sanitary officer, for the successful conduct of the antimosquito crusade. Major Reed, in the paper referred to above, expresses sincere thanks to 'Major-General Leonard Wood, U.S.V., without whose approval and assistance these observations could not have been carried out.'"

For 140 years prior to the late Spanish-American war, Havana had never been free from yellow fever; the annual number of deaths from that disease having averaged from 500 to 1,000, some years as many as 1,600—largely among the Spanish soldiers, great numbers of whom were imported every year up to 1898. During the first two years of American occupation the sanitary authorities devoted themselves energetically to putting the city in good hygienic condition, and especially to measures then considered most effective against yellow fever, such as the destruction and disinfection of fomites and localities supposedly infected by that disease. The result was a rapid decrease of all infectious diseases, except yellow fever, and an enormous diminution of the general mortality rate. Smallpox, which had been a terrible scourge under the Spanish administration, disappeared entirely in July, 1900, and has not returned since. Nevertheless, the amount of yellow fever in the city did not diminish along with other fevers, showing that ordinary sanitary measures had no effect upon it. There was more yellow fever in Havana during December, 1899, than in any December for several previous years. In 1900 there was a sharp epidemic, and in December of that year there were twenty deaths from yellow fever in the city. In January, 1901, there occurred twenty-four cases in Havana. In February, 1901, Major Gorgas, having fully accepted the demonstration of the propagation of yellow fever by mosquitos, turned all the energies of himself and his department to (1) The protection of yellow-fever patients from mosquitos. (2) The prevention of the infection of mosquitos by yellow-fever patients. (3) The destruction, by fumigation, etc., of all possibly-infected mosquitos, and (4) The abolition of all water barrels, pools, and other breeding places of mosquitos in Havana.

Practically no attention was paid to fomites, of which at the time there must have been a great abundance in the city. No attempt was made to get rid of fleas and bed-bugs, by which Havana is, at all times, infested. The result of this concentration upon the mosquito, and neglect of every other supposed cause of yellow fever, was a rapid subsidence of that disease until within less than eight months the last case had occurred in the city; after which yellow fever disappeared entirely. Not a case of it has occurred in Havana since September 27 1901; although during the summer and autumn just ended patients sick with yellow fever, contracted in Mexico and Central America, were frequently carried through the heart of the city from the ships by which they had been imported, to the yellow-fever hospital. During their transportation from ship to shore, and along the streets, they were kept carefully covered with mosquito netting, and upon arriving at the hospital, were placed in wards made mosquito-proof by wire-gauze screens. In the same wards were treated, at the same time, non-immune patients, sick with other diseases, and they were attended by non-immune nurses. That yellow fever is contracted solely from the mosquito is now so firmly and universally believed in Havana, that no one has the slightest fear of patients affected with that disease, provided the said patients be protected from mosquitos and the mosquitos from them.

It is contended by the opponents of the mosquito doctrine that the disappearance of yellow fever from Havana may not have been due to Major Gorga's active anti-mosquito measures; because yellow fever had frequently disappeared, for considerable periods, from Santiago and other Cuban cities. But the conditions were quite different in Havana and the smaller cities. In the latter, the number of non-immunes was always very small, and the epidemic of yellow fever in one of these soon ceased, on account of the consumption of susceptible material; whereas, in Havana, the commercial, military, and yellow-fever center of the island, the number of non-immunes was always large, thousands of immigrants coming into it every year, constituting an uninterrupted and inexhaustible stream of fresh material for keeping up yellow fever in an epidemic form.

All of the many able, cultivated, trained American medical officers—among them such men as General Wood, Surgeon-General O'Reilly, Major Kean, Major Gorgas, Captain Stark, Surgeon Carter, and Surgeon Glennan, and others, who were in Havana, and who had personal knowledge of the mosquito-yellow-fever experiments and demonstrations made there, were, without exception, completely convinced that yellow fever is transmitted to man exclusively by the mosquito. This is exceedingly strong evidence, to my mind, of the correctness of the proposition stated in the title of this paper. Had our distinguished colleagues, who do not agree with us, been on the ground as we were, and seen with their own eyes, as we saw, the exactness and completeness of the proofs, I believe they would have been convinced, as we were.

The idea, held by some able and prominent medical men, that yellow fever may be transmitted by bed-bugs, fleas, and other suctorial insects, is, in the light of our present knowledge of insects and disease, highly improbable. Bed-bugs and fleas are found all over the world, in all climates, and at all seasons of the year; whereas, yellow fever is restricted to certain tropical and sub-tropical regions, and prevails only in the summer and autumn.

Another highly significant fact, in this connection, is that while yellow fever was melting away like ice under a summer sun before Major Gorgas's anti-mosquito operations, the city of Havana was infested with bed-bugs, fleas, etc., galore; no attention being paid to them by the sanitary department, and that the same prevalence of these blood-suckers has continued throughout the subsequent fourteen months, during which the city has remained free from yellow fever.

The transmission of yellow fever by bed-bugs, fleas, or any other living entities, other than mosquitos, would be in violation of an established law governing the propagation of parasitic diseases, of which there are a great many. Each of said diseases, common to man and lower animals, is shared by man with only one other animal. In order to get from one human being to another, its parasite has to pass from man to the intervening animal and thence back to another human being—one variety of tape-worm from man to the pig, and from the pig back to man; another variety of tape-worm from man to the ox, and from the ox back to man; the germ of malarial fever from man to the anopheles mosquito, and from this insect back to man. Very many other similar instances might be cited. Each parasite has its own limited cycle, out of which it cannot live. As Ronald

Ross states: "All these are not theories or fancies, but hard facts, won by science at the cost of immense labors carried out by many scientific men during many years."

Although the germ of yellow fever has not been found (no more has that of smallpox), yet, the scientific and circumstantial evidence is practically positive that it is an animal parasite, whose cycle requires a certain length of time, and is very similar to that of the malarial parasite. We know that the yellow-fever germ goes from man to the stegomyia mosquito and from the stegomyia back to man. No instance has ever been advanced in which there seemed to me even a possibility that yellow fever had been transmitted by bed-bugs, fleas, or flies. Certain it is that no such case has occurred in Havana during the past fourteen months, in which yellow fever has been absent from that city, although, as shown above, unequaled opportunities for such an occurrence have there been constantly in existence.

Carter, in a very able contribution (Yellow Fever Institute Bulletin, No. 11) sums up as follows:

"For the belief that yellow fever is conveyed in nature *only* by a host, and doubtless a mosquito host, we have (1) The analogy of other diseases conveyed by insect hosts. (2) That all facts observed about the propagation of yellow fever agree with the necessary deductions of this theory. (3) No other theory explains all the facts observed of its propagation."

The fact that so many, perhaps all, of the peculiarities and problems of yellow fever, impossible to understand formerly, are explainable and capable of solution by what we know of mosquitos and their relation to disease, is highly interesting and important. A few of these are:

Its singularly restricted area; its dislike for altitude, upper stories, plateaux, mountains, etc.; its partiality for the sea-coast and low-lying districts; its incommunicability from man to man; the meaning of "place infection"; the interval, two to three weeks, between first (infecting) case and subsequent group of cases (Carter); its frequent appearance at sea several weeks after vessels had left port; its arrest by frost and cold weather; its survival through winters; its absence from Asia and India, etc.

Of the problems elucidated by the discovery of the mosquito origin of yellow fever, I cite the knottiest of them all, the second outbreak on board the U.S.S. *Plymouth*, in 1879 (utterly inexplicable to me under the fomites, or any other, theory). The *Plymouth* sailed from New England early in October, 1878; arrived at St. Thomas, W. I. (a yellow-fever stronghold), on October 21, where she went alongside the wharf and coaled ship, remaining until October 25. The officers and stewards were allowed to go on shore during this time. On the 25th she went to Frederickstadt, Santa Cruz. November 4, while at Frederickstadt, a case of yellow fever appeared on board. Between the 4th and 7th seven cases occurred on board. On the 7th the *Plymouth* started north; after which date no fresh cases occurred in the ship. On December 1 she reached Portsmouth, N. H., where the weather is usually cold at that season of the year. From Portsmouth she went to the near-by city of Boston, where she was emptied of her crew and stores, opened up and frozen out during January and a part of February, 1879. The vessel had been several times fumigated with burning sulphur. February 12, 1879, she was recommissioned, and, on March 15, started back to the West Indies. March 19, "the damp berth-deck became very warm; a tropical condition prevailed." March 21, immediately after reaching the tropics, and before she had touched at any port, yellow fever broke out among her crew.

The solution afforded by the mosquito doctrine is simple and satisfactory: The *Plymouth* left the West Indies on November 7, 1878, with fresh yellow-fever cases, and, doubtless, with numerous contaminated mosquitos, on board. As soon as she entered winter weather, about December 1, the infected mosquitos went into hibernation and remained torpid until they re-entered the tropics, when some of them became active and stung certain of the men, thereby giving two of them yellow fever.

That mosquitos hibernate is a well-known fact. Theobald, in his standard monograph, states that mosquitos hibernate in the extreme cold of the arctic regions; that the gravid females seek shelter as soon as the weather becomes cold, lie dormant all winter, and deposit their eggs in early spring. Howard, the highest American authority upon the subject, says in his capital work ("Mosquitos," page 6): "Mosquitos hibernate in the adult condition." In conversation with this distinguished entomologist in Washington the other day (November 22, 1902), Howard used these words, which I took down verbatim: "The stegomyia hibernates in the adult stage. I have a strong suspicion that it hibernates in the egg stage also."

Too much admiration cannot be accorded to Major Gorgas for the superb manner in which he accomplished the deliverance of Havana from yellow fever. In planning and conducting this creative work, without any precedent to guide him, he showed not only consummate administrative and executive ability and foresight, but also genius of a high order. After it was finished it was impossible for us to look back upon it and point out any particular in which the work could have been improved.

At the recent meeting of the Conference of State and Provincial Boards of Health of North America, at New Haven, Conn., it was resolved concerning Major Gorgas's sanitary redemption of Havana, that, "we regard (it) as one of the most brilliant achievements of the application of sanitary science to public health work ever accomplished."

The Meaning and Significance of Leucocytosis.—Robert N. Willson says that the term leucocytosis must include every increase in the absolute number of the leucocytes of the blood examined, as well as every increase in the percentage counts of the various leucocytic forms. A leucocytosis, of whatever nature, must always be regarded as a sign of clinical importance, but never of such weight as to influence against equally convincing physical signs. A high percentage of the polymorphonuclear forms in the absence of an absolute leucocytosis indicates the presence either of pus or of some grave inflammatory process, together with a low vitality of the patient. Single counts of the leucocytes, or single estimations of the leucocytic percentage, are often misleading, while a persistent series of observations will seldom fail to aid in the diagnosis and treatment of the condition. A gradual, but steady rise in the total count of leucocytes above the customary number, usually indicates the presence of an active and augmenting inflammatory influence. When this increase reaches large proportions it may be looked upon as an indication of the presence of an active leucocytic process (serous or purulent effusion, localized pus collection, pneumonic exudate, etc.), provided the clinical picture also bears out the suggestion.—*Proceedings of the Philadelphia County Medical Society.*

ANKYLOSIS OF THE CRICO-ARYTENOID ARTICULATION, DUE TO ACUTE INFLAMMATORY CAUSES.*

By D. BRYSON DELAVAN, M.D.
NEW YORK.
CONSULTING LARYNGOLOGIST TO SAINT LUKE'S HOSPITAL, ETC.

THE condition known as ankylosis of the crico-arytenoid articulation is one which has been recognized and fairly understood for years. Various distinguished writers have exploited it, some of them in comprehensive articles. Either they have not expressed themselves with sufficient emphasis as to certain of its features, or else the subject has failed to attract the general attention which its importance deserves. Nothing is more common than to find that a case of laryngeal ankylosis has been mistaken for one of paralysis, and that to prove the existence of the latter fruitless efforts have been made to demonstrate some condition capable of producing pressure upon or injury to the recurrent laryngeal nerve.

It should be more generally known that ankylosis of the arytenoid is not exceedingly rare, that it may result from comparatively simple causes, and that it may be present in an otherwise healthy subject.

Laryngeal ankylosis may exist under varying conditions. It is not the intention of the writer of this article to deal with those cases in which the fixation of the arytenoids is bilateral, nor with those complicated with extensive cicatrization of the larynx due to former destructive lesions. In the latter cases the condition is obvious and diagnosis easy. The cases which present especial difficulty, however, are those in which there is no visible suggestion in the larynx of former disease, and in which, between simple fixation of one crico-arytenoid joint on the one hand and a genuine paralysis of the muscles controlling its movements on the other, no apparent difference can be discovered. It is this type of the affection in which confusion arises and in which radical errors of diagnosis are commonly made.

The majority of cases of laryngeal ankylosis have been supposed to be due to perichondritis resulting from syphilis, gouty or rheumatoid arthritis, cancer, and tuberculosis. The exanthemata, diphtheria, and various traumatisms may also be followed by it. Many cases, however, are the result of inflammatory conditions of a more simple nature, and it is in such instances, as well as in cases following the exanthemata, that errors of diagnosis appear to be most commonly made. Occurring as the immediate effect of a violent acute local inflammation, there should seldom be any doubt as to the true character of the lesion. When, on the other hand, a case presents itself long after the date of the original causative attack, the differential diagnosis between ankylosis and paralysis is not always easy, especially when a clear history of acute laryngeal inflammation has not been obtained. From among a number of cases seen by the writer at various times during a considerable period of observation those herewith presented have been selected as being especially illustrative. Any acute inflammation of the posterior region of the larynx attended with infiltration may cause a temporary fixation of the crico-arytenoid joint. Thus, in the following case is shown one of the processes by which such a condition may be produced.

CASE I—*Acute Laryngitis, Temporary Fixation.*—Male, aged twenty years. This patient had a violent acute pharyngitis, with follicular tonsillitis. Examination of cultures failed to demonstrate the presence of diphtheria. Following this there was an acute laryngitis attended with much swelling of the left arytenoid, which, with the whole of the left side of the larynx, was almost immovable, with the vocal band in the median line. There was considerable œdema, pain, and dysphagia. Under ordinary treatment the inflammation subsided and the natural movements of the left side of the larynx were completely restored.

Such cases as this are by no means uncommon. It is easy to understand that under more violent or longer-continued inflammation, a genuine perichondritis might be excited, through which the fixation might become established to a permanent degree.

CASE II—*Phlegmonous Pharyngitis Causing Unilateral Crico-arytenoid Ankylosis.*—Male, aged forty years, a native and resident of Yucatan, referred to me by Dr. Desvernine of Havana. Laryngoscopic examination showed fixation of the right side of the larynx in the cadaveric position. Patient had syphilis twelve years ago, but had lately been under treatment with no effect in ameliorating the condition of the throat. Tuberculosis was excluded, nor was there evidence of old pleuritic thickening, nor any distinct evidence of disease of the greater vessels on the right side of the thorax. This latter feature of the case was investigated with greatest care, the patient finally having a radiograph of the chest taken by Dr. Williams of Boston without any positive results. Leprosy is common in Yucatan, but there was present no symptom whatever of it. There was no infiltration, the failure of motion was not such as is commonly seen in epithelioma of the larynx, there was absence of lancinating pain, of swelling outside the larynx and of glandular involvement. The hoarseness had existed for a number of weeks. After an elaborate series of investigations had been brought to a close this patient finally remembered to explain that several months before he had suffered from a violent phlegmonous inflammation of the pharynx, in the course of which the right tonsil was greatly enlarged and suffocation was threatened. Had this fact been elicited at the outset much labor and loss of time would have been spared, for this case is precisely similar to the others of its class herein recorded. There was no paralysis, but there was ankylosis originally due to an acute perichondritis. In this case the patient was advised to reassure himself as to the existence of serious organic trouble, to return home, and to carry out the plan of treatment rationally indicated.

CASE III—*Unilateral Ankylosis Following Diphtheria.*—Female, aged forty years. Twenty years before my first examination she had a severe attack of laryngeal diphtheria. Since that time her voice has been altered in quality, vocalization has always been more or less difficult and on many occasions the patient has been aphonic. At times she has suffered from obstructed breathing, especially when the pharynx and larynx have been congested from colds or other causes, and on several occasions the dyspnœa has been severe. Laryngoscopic examination showed fixation of the right arytenoid in the cadaveric position. Careful investigation failed to reveal any cause of pressure upon the right recurrent laryngeal nerve, or any evidence that it had been in any way injured or diseased. The fixation of the joint was absolute. The treatment carried out in this case has been followed by excellent results. It has consisted in attention to the general condition of the patient and in immediate measures to stop a beginning cold or, if this has failed, to reduce as far as possible the violence of its symptoms. Although this patient has been obliged to reside in a particularly irritating climate she has been able to fill an

*Read before the Section on Laryngology, New York Academy of Medicine.

important social position with conspicuous success. Not always, however, with entire comfort to herself. She has been advised as to the nature of her trouble, and the importance of any sign of further closure of the glottic aperture.

Since recording the above, four years ago, the patient has recently been examined. During this time she has passed the climacteric. The condition of the throat is now in every respect vastly improved, all congestion and thickening in the soft tissues of the larynx has disappeared, the vocal bands appear to be of normal whiteness, the voice is fairly strong and of good quality. The position of the right side of the larynx remains unaltered. While the excursion of the left arytenoid is exaggerated on account of the position of the right vocal band beyond the median line, this very fact is an advantage in the matter of breathing, as the glottic aperture is thereby distinctly increased in diameter. This patient reports a remarkable increase in the power of chest expansion during the past five or six years. She is in perfect health.

Case IV—*Unilateral Ankylosis, Following Diphtheria.*—Female, aged nineteen years. When a child had a severe attack of laryngeal diphtheria. This was followed by permanent hoarseness of the voice. Examination of the larynx showed fixation of the right crico-arytenoid joint; the arytenoid was immovable. There were no signs of paralysis of the recurrent laryngeal. The voice was hoarse, rasping and weak. The patient had never experienced any marked difficulty in breathing. This, like the preceding case, was one of ankylosis of the right crico-arytenoid joint, due to violent inflammation of the larynx caused by diphtheria.

Case V—*Complete Ankylosis of Right Crico-arytenoid Articulation Following Typhoid Ulceration of the Larynx.*—Male, aged thirty-five years. The patient suffered from an attack of typhoid fever attended with numerous severe complications and sequelæ. About the sixth week of the progress of the enteric disease the voice became hoarse, and pain and difficulty in swallowing began to be present. Examination of the larynx revealed intense congestion throughout the whole of its interior and in the neighborhood of its upper limits, most marked upon the right side. This congestion increased rapidly, the focus of the inflammation being apparently inside the larynx and toward the right of the posterior commissure. At this point an ulcer quickly developed. The latter was peculiar in character and distinctly different from any of the lesions commonly met with in this locality. It was about three-eighths of an inch in diameter, deep, destructive, and surrounded by a zone of fiery inflammation. In view of the nature of the general attack, the peculiarities of the lesion and the liability of various parts of the upper air tract to infection during the progress of typhoid fever, the diagnosis, typhoid ulceration of the larynx was obvious. The progress of the laryngeal disease was rapid and severe, and from beginning to end the symptoms were such as to excite the greatest apprehension. Following the first appearances of congestion in the larynx, tumefaction of all its soft parts took place to such an extent as to imminently endanger the patient's life. Thus all of the neighborhood of the posterior commissure and the arytenoid cartilages, the false vocal cords and the epiglottis quickly became œdematous, the œdema advancing day by day until dyspnœa became urgent. Meanwhile, as the result of the severe and long-continued illness, the patient's general condition was most grave, and any attempt at tracheotomy would have been attended with serious results, the heart action being particularly feeble and uncertain. It was thought best to watch the case with unremitting care, to control the local conditions as well as possible by local means, and in case of necessity, resort to intubation. The duration of the urgent laryngeal symptoms was about ten days. At the end of this time they began to show signs of improvement, the laryngeal ulcer took on a more healthy aspect, the surrounding œdema subsided, and the general comfort of the patient was increased. Although the symptoms present during the height of the attack gradually improved, the patient remained aphonic. During the early part of the attack, as the inflammation progressed, the movements of the arytenoids became restricted, especially upon the right side; here they finally ceased, the vocal band being fixed a little to the right of the median line. With the subsidence of the inflammation the loss of motion upon the left side gradually disappeared, and the full excursion of the arytenoid in abduction was re-established. Not so with the right; from the time when the inflammation had reached its height all motion was absolutely lost. The aphonia, however, began to disappear as the soft parts regained a more natural condition. A lapse of several years finds this patient in perfect and robust health. The chest expansion has markedly increased. The right side of the larynx is still fixed, but the voice is of good strength, and quality, excellent carrying power, and capable of almost incessant use. During the early part of the convalescence a physician was consulted who mistook the case for one of abductor paralysis. Reasoning that since pressure upon the recurrent from an aneurysm is usually on the left side, and that here the supposed paralysis was upon the right, he therefore, informed the patient that he was probably developing a mediastinal tumor. The effect of this was great shock and discouragement, from which it is evident that when fixation follows the history of violent acute inflammation of the larynx, the possibility of ankylosis should always be kept in mind.

Case VI—*Bilateral Fixation Following Typhoid Fever.*—Male, aged twenty-three years, United States. About two years ago he had a severe attack of typhoid fever. Was unconscious for a month, during one week of which time he was comatose. Had hemorrhages from the bowel. During his illness urgent dyspnœa occurred necessitating tracheotomy. Since then and up to the present time has never been able to dispense with the tube. His power of speech is good, the voice simply showing a roughened quality. During the day he is able to breathe with the tube plugged, but when asleep suffers from dyspnœa, unless the tube is open. The vocal bands cannot be normally separated and are in a position resembling that present in abductor paralysis. To this effection the condition was attributed. This case is evidently one of ankylosis following typhoid involvement of the larynx. The patient is otherwise strong and well and gives no evidence of any condition which would lead to paralysis of the recurrent laryngeal nerves.

The six histories above quoted represent fairly the type of cases especially referred to in this paper. Thus case No. 1 illustrates the simplest condition of its kind. Before the inflammation had become sufficiently violent, or had continued long enough to cause a marked perichondritis and permanent fixation, resolution began, and the normal function of the part was quickly restored.

Case No. 2 is similar to No. 1 in kind, but differs from it in the severity and duration of the inflammatory attack. In this the final result was permanent disability. Cases 3 and 4 were without reasonable question due to a severe inflammation of the larynx

attending an attack of laryngeal diphtheria. In both of these cases the fixation of the arytenoid was not discovered until years after it had taken place. In case No. 5, due to typhoid ulceration, the exact condition was recognized from the outset. Nevertheless, it seemed impossible to devise any means by which the permanent fixation of the joint could be avoided. With an inflammation so violent, long-continued and profound, destruction of the delicate mechanism of the crico-arytenoid articulation was inevitable.

In all of the above cases the disability was unilateral. In all breathing was accomplished with a fair degree of comfort and success, excepting temporarily in one or two instances when the patient suffered from congestion of the larynx. Case No. 6 was bilateral. In it the continuous wearing of a tracheal cannula has been necessary.

It is evident that the differential diagnosis between crico-arytenoid ankylosis and paralysis of the recurrent laryngeal nerve may, in some cases, be very difficult. In many instances it must rest upon a careful process of exclusion. In cases of recent paralysis the absence of fixation of the joint may be proved by pressing against the arytenoid cartilage with a laryngeal probe, and thus causing it to move about. In ankylosis no marked change of position would be possible. This test is invalidated, however, when the paralysis is of long standing, by reason of the tendency in such cases to gradual fixation of the joint from disuse. While actual fixation from whatever cause may amount, practically, to one and the same thing, fixation from peripheral inflammation does not necessarily imply a grave underlying cause. Paralysis, on the other hand, may be due to the presence of some deep-seated disease of serious importance, such as thoracic aneurysm, mediastinal growth or central nervous lesion, and thus be attended with extreme danger. The statement has been made that in incomplete unilateral ankylosis of a vocal cord there is some perceptible inward movement of the arytenoid on phonation, while in simple paralysis of one vocal cord without ankylosis the arytenoid cartilage on the paralyzed side during phonation is displaced by the sound and over-adducted arytenoid. Attention to this point sometimes enables one to distinguish between a paralyzed vocal cord and simple fixation of the cord due to disease of the crico-arytenoid articulation, for in the latter case the healthy arytenoid approaches, but does not displace, that on the affected side. Remembering that a paralyzed vocal cord becomes more or less fixed from disuse the diagnostic point has greater positive than negative value. Actual fixation of the joint, the history of some severe local inflammatory condition and the absence of signs of thoracic, mediastinal, or central disease, should fairly establish the diagnosis of crico-arytenoid ankylosis. It is unnecessary to say that the prevention of crico-arytenoid fixation in cases in which this condition is threatened, is most desirable.

Just how it may be successfully accomplished, however, is not easy to say. Beyond the means in ordinary use for the control of the causative inflammation, there are no methods known which are especially adapted to reach this particular end. Certain prophylactic measures, however, have occurred to the writer as worthy of mention. Thus, in typhoid fever, thorough and systematic cleansing of the nasal cavities and mouth is productive of marked benefit. Probably few perforations of the nasal septum from typhoid ulceration occur in patients thus carefully treated. Typhoid ulcer of the larynx proverbially occurs in cases in which prostration is extreme and in which the patient, through mental hebetude, has been unable to free his throat from accumulated secretion. Greater attention to this detail, as above suggested, might reduce the number of bad results, both as to the risk of ankylosis and even to life in these almost uniformly fatal cases. In diphtheria the statistics of ankylosis are likely to be materially lessened since the introduction of antitoxin has shortened the progress of the disease and brought its laryngeal manifestations under so much better control. There is no excuse for laryngeal ankylosis to occur after smallpox, since, with vaccination, there is no excuse for the disease itself. When it is present, however, the same suggestion might be advanced as the one given already for typhoid disease.

Simple severe phlegmonous inflammation of the pharynx is at once commonly seen and hard to deal with. When a tendency to fixation appears during such an attack it is not only important that the most effective means possible to subdue the inflammation should be used, but diligent pains should be taken during its subsiding stages to cause complete resolution and speedy relief of all remaining local congestion. Thus, the patient should not be dismissed at once, but should be kept under observation and under the use of topical applications as long as the latter can be of benefit. When fixation has become established as the result of inflammation of a more or less chronic character, or of lesions attended with much thickening and deformity of the surrounding parts, and especially when it is bilateral, the indications may require radical measures in order to overcome the resulting stenosis and enable the patient to live, even to the permanent wearing of a tracheal cannula. Where this is the case the wearing of a cannula with a valve attachment is useful, in that it imposes a certain amount of exercise upon the larynx, and thus tends to improve the voice and increase the breathing space. Again, in certain exceptional cases attempt may possibly be made to enlarge the glottis by means of various kinds of dilators. By far the best of these is the O'Dwyer tube, introduced in graded sizes and worn for considerable lengths of time. Generally speaking, however, and in particular with regard to the class of cases referred to in this paper, attempts at dilatation have not yielded encouraging results, the mechanical difficulties present being of so serious a nature that no known method seems to meet them.

The general opinion with regard to their management is that if the breathing space be sufficient, the best policy is to subdue any existing inflammation as quickly and as thoroughly as possible and then to avoid all interference, especially of a mechanical nature, which might tend to further irritate the parts and continue the inflammatory process in the joint.

A conservative feature of these cases seems to be that in most of them the fixation is not directly in the median line but a little to one side of it, the vocal band being in the so-called "cadaveric position." While this imposes more work upon the opposite and movable vocal band in the act of phonation, it creates a wider glottic space and thus lessens the danger of dyspnœa.

It must always be remembered that undue labor is thrown upon the movable joint, both in breathing and in phonation, and that therefore the patient should both observe moderation in the use of the voice and also that he should study carefully the best methods for economizing its production.

Much help has been gained in such cases, under good teachers in vocalization through courses of vocal gymnastics properly selected for the strengthening and developing of the vocal muscles.

An interesting point in connection with the cases reported herewith is the marked increase in chest expansion noticed in several of them. The effort

necessary to produce a given volume of tone is much greater than normal In order to compensate for this the victim of laryngeal ankylosis should practise gymnastic exercises calculated to strengthen the chest and increase its expansion.

Another important factor is the avoidance of all causes of local irritation, whether from climate, surroundings, or occupation. Laryngeal congestion of every sort should, if possible, be prevented, and when present should be relieved as quickly as possible. Acute catarrhal attacks should be at once treated. Causes of laryngeal congestion, such as nasal stenosis, diseased conditions of the tonsils and elongation of the uvula should be removed, and every effort made to strengthen the throat and overcome any existing tendency to taking cold.

Under fairly favorable conditions a large majority of the patients whom I have seen have not been prevented from carrying on the ordinary affairs of life. In a number of instances they have been persons engaged in pursuits which have required more or less constant speaking, several of them having been in public life. In one or two cases the laryngeal fixation had been in existence long before it was recognized, the patient not having been aware of any loss of function beyond slight huskiness of the voice. Most of these patients have enjoyed excellent health, and their success in life has been very little impaired. Supposing such a person to be within easy reach of good medical aid, in case of accidental dyspnœa, it is probable that as an insurance risk he would make a reasonably safe candidate.

Extensive articles upon this subject have been published by Sir Morell Mackenzie (MEDICAL RECORD, January, 1879), and by F. Semon (*Medical Times and Gazette*, September 18 *et seq.*, 1880). In recent American treatises upon diseases of the throat little or nothing is said of it. Excellent presentations of the subject are given by P. Watson Williams, in his textbook upon "Diseases of the Upper Respiratory Tract" (Longmans & Co., 1901), and by W. E. Casselberry in the new edition of "A Reference Handbook of the Medical Sciences." Vol. V, 1902 (Wm. Wood & Co.). The condition is certainly of sufficient importance to warrant more exact knowledge and more careful attention than the authors of our many recent works upon diseases of the throat have shown.

Sequelæ of Typhoid Fever as Related to the Eye, with Especial Reference to the Accommodation.—George H. Price discusses the condition of paresis or paralysis which so often follows typhoid fever. From clinical and from pathological studies made, the condition can be assumed to be as follows: The axones from the motor nerves of the ciliary ganglion distributed through the ciliary nerves to the muscular apparatus residing in the ciliary body, which is quite vascular, are subjected to the typhoid bacillus carried by the blood, until there is set up a neuritis, which, extending back to the ganglion, induces changes in the nutrition of these cells, which may go on from simple disturbance to complete destruction of the cells. Since the author has studied the pathology, as reported by Nichols, he is of the opinion that the most reliable means of combating the condition lies in some preventive measure; that is, some internal medication during the progress of the disease which will prevent, if possible, the complication to such a marked extent of the nervous system. During convalescence he would suggest that the patient refrain from any near use of the eyes, so as to prevent any taxing of the nerve supply and muscular mechanism while it is yet unable to stand this strain, and which would keep up the irritable condition.—*Nashville Journal of Medicine and Surgery.*

THE RELATIONS AND TREATMENT OF FOLLICULAR CONJUNCTIVITIS AND TRACHOMA.

By ELLICE M. ALGER, M.D.,
NEW YORK.
INSTRUCTOR IN OPHTHALMOLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; OPHTHALMOLOGIST TO THE NORTHEASTERN DISPENSARY.

THE acts of the United States Government excluding immigrants suffering from contagious eye diseases, and of the various local boards of health refusing school privileges to children afflicted in the same way, have given a new importance to the differential diagnosis of two diseases which, while resembling each other very closely at certain stages, may be very different in their cause, contagiousness, and amenability to treatment. This becomes still more important when, in addition to negative measures, such as the denial of privileges to the diseased, we come, as we must eventually if we are logical, to compulsory, positive measures involving operation under an anæsthetic.

Most textbooks on ophthalmology give differential descriptions of follicular conjunctivitis and the early stage of trachoma, but a comparison will show how absolutely useless most of them are for clinical purposes, and to one familiar with dispensary work the confusion of school inspectors, and even of trained ophthalmologists is as obvious as it is explicable.

Fuchs, who has written one of the most widely-read textbooks on the subject, insists on a distinction between the two diseases, and his contribution to clarity is this:

"It still remains to speak of follicular conjunctivitis with regard to trachoma. The former is found chiefly in children, while trachoma is seldom met with in children, but the two diseases are very similar in that lymph follicles occur as characteristic formations in both. . . . But these characteristics are so obscured that even experts cannot, in many cases, make the diagnosis with certainty, and the subsequent course of the disease alone affords the desired information. Even in the histological structure no thorough-going distinction can be found between the follicles and trachomatous granulations. . . . It is therefore easy to understand that these two diseases have been repeatedly confounded with each other, and a number of authorities explain follicular catarrh as being a kind of trachoma distinguished by its mildness and freedom from danger. But to such a view the following objections must be raised: It is not yet certain whether follicular catarrh among confined bodies of men is propagated by infection like trachoma or is merely the result of the contamination of the air by dust, exhalations, etc. On the other hand, it is quite satisfactorily established that under certain circumstances follicular catarrh can arise without any infection whatever. The prolonged instillation of atropine is followed in many persons by the development of a typical follicular catarrh with numerous follicles. But trachoma can never originate without infection. A further and more important distinction between the two is the course. Follicular catarrh is not associated, or only to an inconsiderable extent, with papillary hypertrophy of the conjunctiva, it never leads to shrinking of the conjunctiva or pannus, or any of the other sequelæ. It is a disease perfectly devoid of danger, and one which, without any treatment, finally gets well and leaves no trace behind."

If these facts are so, and they agree with the experience of most ophthalmologists, trachoma is rare among children. Most of the patients who are being excluded from our schools are suffering

from a disease which gives no subjective symptoms, is in many cases at least non-communicable, disappear eventually with or without treatment and leaves no trace behind. If these facts are true, there is no adequate ground for the alarmist statements about the enormous increase of trachoma in the schools. A systematic examination has simply revealed many cases of a harmless disease of which the patient was utterly unaware, and which may or may not be contagious. These unfortunate children are not threatened with any lifelong disability from blindness, and our hospitals can be relieved of the burden of providing for a multitude of children who are not likely to suffer any danger from being treated at home.

Follicular conjunctivitis is simply the reaction through the lymphatics of the conjunctiva to local irritation, and the irritation may be chemical, mechanical, or bacterial in its nature.

In certain individuals the continued instillation of several substances, such as atropine, eserine, hyoscyamine, etc., will be followed by a conjunctivitis marked by the development of follicles in the conjunctiva of the lids, and especially of the fornix. On the lids they are small, round granules, not larger than pinheads, because they are restricted by the close adhesion of the membrane to the lid, but in the loose tissue of the fornix they are much larger, resembling frog spawn or grains of boiled sago. When the lower lid is everted, they often appear to be arranged in parallel rows like beads. The microscope shows that these granulations are simply collections of adenoid tissue. This is evidently not an infectious process, for it occurs in the presence of sterile solutions, and results evidently from chemical irritation, subsiding gradually after discontinuance.

Recent investigations have shown that on the street level bacteria are from seven to forty times more numerous in the slums than in more sparsely settled neighborhoods, and the disproportion of dirt is even greater. It seems perfectly natural that the strumous child who spends his days in the dusty street and his nights in the smoke and indescribable atmosphere of the tenement should have a follicular catarrh, while the child of the well-to-do escapes. The development of lymph follicles in his conjunctiva seems as natural and common as the development of his other lymphatic enlargements, and is not any more likely to be the result of special infection than they are. Follicular conjunctivitis occasioned in this way gives rise to no particular symptoms, is frequently only noticed at the physician's examination, and is certainly not contagious.

But bacterial irritation may also cause symptoms which are identical in every respect, even to the microscopic anatomy with those caused by chemical and mechanical irritation. It is probable that any one of several bacteria might cause a similar reaction which would vary in its effect and contagiousness according to the virulence of its cause. This would explain the very great diversity of opinion amongst bacteriologists as to the cause of this disease. The conditions under which we find the disease occurring agree with the theory of its cause. It occurs most frequently in children who are of the so-called strumous type, who are pale and anæmic and have glandular enlargements in all parts of the body. It is particularly prone to occur among those who are crowded and dirty. It seems to have a special affinity for the Jews, the Italians, and the Irish. These facts might be construed as indicating contagion. On the other hand, it is said to be equally frequent among children of the dusty plains, who are certainly not crowded, and it is almost unknown in the pure atmosphere of the mountains.

Trachoma must be sharply distinguished from this trivial affection. According to the textbooks, it appears either in the granular form which may be indistinguishable clinically or microscopically from folliculitis, or in the papillary form with hypertrophy of the conjunctiva which takes on a velvety appearance. As a rule, the two forms are said to be mixed, the papillation occurring mainly on the lid and the granules in the lesser tissues of the fornix. This seems to be the whole source of confusion between the two diseases. The essential feature of trachoma is the hypertrophy of the conjunctiva. Without this there can be no future development of scar tissue and the disease is a trivial one. The occurrence of lymphoid masses indistinguishable from those of folliculitis should be considered as an epiphenomenon and not an essential part of the disease. A general enlargement of the glands occurs in constitutional syphilis, but few argue nowadays that general adenopathy alone is enough to base a diagnosis on. So trachoma is a disease causing much irritation and consequent hypertrophy of lymphoid tissue, but this same hypertrophy may be due to entirely different causes, as we have seen, and, by itself, is utterly insufficient as a basis for diagnosis. Such a diagnosis is mere guesswork, with the probabilities much against its correctness. Until bacteriology finds a specific cause for trachoma, we should depend on the presence of true conjunctival hypertrophy.

The subjective symptoms of real trachoma are noticeable. The patient complains of gluing of his lids, photophobia, a sensation of sand in the eye, the upper lid is partly dropped, and there is more or less purulent discharge. In a fresh case the whole eye looks red, but in a chronic case the redness may be hardly noticeable and the discharge very slight and watery. In a portion of the cases injury to the cornea follows, either ulceration or pannus. The cornea becomes hazy and irregular, and gradually a growth of vascular new tissue begins at the margin and spreads toward the center, especially under the upper lid. This eventually leads to a permanent opacity. When the thickening of the conjunctiva has reached a certain height, a process of cicatrization begins and continues till the hypertrophic tissue has been replaced by a thin, white scar, and it is from the contraction of these scars that some of the most troublesome sequellæ come. The commonest results which are in direct proportion to the amount of scar tissue are ptosis, entropion and ectropion. As regards vision, the permanent opacities of the cornea are most to be dreaded. It is these results which ophthalmologists and sanitarians have in mind when they advocate such paternal care over diseased eyes, but though the results pictured are sufficiently dreadful they must follow a very small percentage of cases, for real trachoma is comparatively rare among those born in this country. Trachoma is certainly a contagious disease of which numerous epidemics are recorded, but pathologists have been unable to agree on an exact cause: there may be several organisms. In Egypt, which was its original home, the gonococcus has been found in a large number of acute cases and very similar appearances have been observed in chronic gonorrhœal infection of the eye. Several observers have isolated organisms closely resembling that of Neisser. On the bacteriologist, however, we must eventually depend, for his are the only tests which will determine for us the degree of

contagion, the prognosis, and the appropriate treatment of any given case.

The confusion of diagnosis between the two diseases has led to an equal confusion in the treatment. It has been considered almost an ideal result in true trachoma to get finally a white thin pliable scar, not capable of contracting unduly, or of causing irritation of the corneal surface, and too many men have been led by the pursuit of this ideal to treat with caustics like bluestone and strong nitrate of silver follicular conjunctivitis which would not develop scars naturally even if left entirely without treatment. It should be remembered that in this disease the essential element is lymphatic hyperplasia, and the treatment I have found most successful has been based on the treatment of lymphatic enlargements in other portions of the body. First, so far as possible, the cause of irritation, whether chemical, mechanical, or bacterial, should be removed. This often involves, not only frequent irrigations of the conjunctiva with boric-acid solutions, but should also consider, so far as possible, the physical conditions and surroundings of the child. Most of them are better for the use of cod-liver oil and iodide of iron. Locally, I have obtained by far the best results by applying with a swab, at least three times a week, a solution consisting of

℞ Ichthyol..... ♏ xv.
Tr. iodi..... ℥i.
Glycerin..... ℥i.
Sig. Apply to conjunctiva with brush.

Such treatment seems to me to be rational and productive of better results than any other method I have tried. As the conjunctiva improves, this solution is brushed in with increasing vigor. It is much less painful than either the bluestone or the silver nitrate. On the alternate days an instillation of the following is made at home:

℞ Zinc sulph..... gr. i.
Vin opii..... ♏ viii.
Aquæ..... ℥ss.
M. Sig. One drop in each eye t. i. d.

Of course the result depends in a great measure on the home surroundings and care of the child, but I have frequently seen a typical frog spawn conjunctiva become perfectly normal in three weeks. The use of the roller forceps I consider certainly as a great time saver, even though it generally involves some after-treatment. In children, however, their use requires a general anæsthetic. Expression is not a necessary part of treatment, and the vast number of cases must be treated without it.

The treatment of real trachoma is a very different matter, and since one cannot predict in a given case the height to which the conjunctival hypertrophy will reach, he is equally unable to say whether the disease has been modified by his treatment or has simply reached its natural limit. In the same way the development of scar tissue is in direct proportion to the preceding hypertrophy, and may or may not have been influenced by treatment. Bearing in mind that in many cases a germ analogous to the gonococcus has been found, it would seem that in the acute cases the use of silver preparations was rational. In chronic cases it has frequently happened that the results of an acute inflammatory process such as that caused by the accidental inoculation of urethral pus or the deliberate use of an infulsion of jequirity has been followed by improvement. If mangling the conjunctiva with trachoma forceps does any good, I believe it is in this way. Personally, I have made use of the ichthyol, iodine, and glycerin mixture above alluded to, and if the results have not seemed to me better than under other plans of treatment, neither have they seemed any worse.

117 East Twenty-sixth Street.

The Prognostic and Therapeutic Importance of Arterial Pressure.—Ch. Jourdain and G. Fischer state that the chief factors in the production of variations in arterial pressure are first toxic, then nervous, and finally mechanical. The pathological results of the changes in the arterial pressure are first, *Functional*, due to changes in the action of the heart, in the blood vessels, and in the blood mass; infectious diseases, anæmia, pleuritic exudations, icterus, etc. These changes are temporary merely. Second, *Essential*, produced by permanent causes, by anatomical conditions of the circulatory apparatus (confirmed arteriosclerosis, valvular lesions, interstitial nephritis). The functional changes have a very great importance in prognosis; the essential merely confirm a diagnosis. As to treatment, the best remedies in hypotension consist of vasomotor medication, and above all, in the subcutaneous injection of saline solutions. In hypertension, a lacto-vegetable diet is of prime importance, with general and abdominal massage. The latter is indicated chiefly in hypertension of the portal system. Several successive bloodlettings are frequently of value.—*Revue de Médecine.*

Purulent Mediastinitis.—Professor Kopistein states that the etiology of cases of this affection may be classed under three heads, injury, surroundings, and infection, or, more properly, metastases. The diagnosis is admittedly very difficult, depending largely on the previous history, but the presence of pain and fluctuation may assist. The prognosis under any circumstances, is bad, as death by sepsis or by perforation of an important organ, determines the fatal result. The treatment must, of necessity, be largely empirical, until pus has formed and the diagnosis been conclusively proved. The first step would be a "Priessnitz" compress over the sternum. Galenus suggested trepanning the sternum and exploring for pus. When fluctuation appears in any of the intercostal spaces it should be early opened and the abscess evacuated, enlarging the opening, as far as possible. With this object Heyfelder has practised resection of the sternum in fifteen cases with the best results. Milton has sewn through the sternum in the middle and chiselled a portion out on both sides.—*Medical Press and Circular.*

Cæsarean Section Ten Minutes after Death of the Mother; Child Alive.—W. J. Fletcher, J. S. Webster, and W. J. Wilson report the case of a woman who died of cerebral hemorrhage. As the fetal heart could be heard, cæsarean section was rapidly performed, the cord cut and let bleed for awhile, artificial respiration resorted to, and the lungs inflated by blowing in the mouth. After forty minutes' steady work the child was breathing freely. It lived twelve hours. The result might have been better for the child if delivered sooner, as suggested by Dr. Fletcher, but the friends would not at that time consent to the section.—*Canadian Journal of Medicine and Surgery.*

A Report of Thirty Cases of Œdema, Apparently Epidemic in Character.—Halsey Dewolf describes these cases in detail, and says that the most reasonable theory which presents itself in explanation of this unusual epidemic of œdema is as follows: A period of severe bowel disturbance occurring in these patients rendered them susceptible to some common infection, possibly acquired from the milk; this infection, spreading from the gastrointestinal tract, produced pathological changes in the blood and blood vessel walls, besides affecting to a greater or less degree the kidneys; as a result of which changes there appeared the œdema.—*Archives of Pediatrics.*

THE STUDY OF MAN.

MR. ARTHUR MACDONALD of the United States Bureau of Education, who is favorably known as a writer on criminal sociology and allied subjects, has recently mapped out a plan for the study of man with reference to bills to establish a laboratory for the study of the criminal pauper and defective classes.

The study of man to be of most utility must be directed first—thinks Mr. Macdonald—to the causes of crime, pauperism, alcoholism, and other forms of abnormality. To do this the individuals themselves must be studied. As the seeds of evil are usually sown in childhood and youth, it is here that all investigation should commence, for there is little hope of making the world better if the causes of social evils are not sought at their beginnings.

The most rigid and best method of study of both children and adults is that of the laboratory with instruments of precision in connection with sociological, pathological, and abnormal data as found in children in criminal and defective classes and in hospitals.

It has consequently been proposed to conduct such investigations under the United States Government, by the establishment of a psychophysical laboratory, as the collection of a large number of such data concerning a mass of individuals, and the computation, tabulation, and publication of the results could not easily be undertaken by an individual or by a university, because of the expense involved.

Bills or amendments to establish a laboratory to study the criminal pauper and defective classes have been introduced into Congress by Senators Hoar, Nelson, Bacon, McComas, Quay, Penrose, Money, and Pettigrew, and by Representatives Ray and Henry. The general purpose of these bills is a sociologic and scientific study of the abnormal classes, it being understood that such study is a development of work already begun under the Federal Government.

Mr. Macdonald, in referring to university laboratories, states that a large number of these have been established, but that their usefulness is limited, insomuch as they were intended mainly for pedagogical purposes. Therefore he argues that there is need of a different kind of laboratory, one not pedagogical, but sociological and practical, and of more utility to society directly.

The study of children is naturally of the first importance, but is, as yet, only at its beginning. It is not definitely known, for instance, whether a child inherits his mental and physical characteristics, or whether environment is the chief factor in the formation of good or evil habits.

If it could be ascertained, more or less accurately, whether there were mental and physical characteristics peculiar to unruly children in school and criminal children in reformatories, or to dull school pupils and feeble children—characteristics distinguishing such children from the normal child, we might foresee special dangers to these children, and thus protect many from temptations and conditions that otherwise would ruin them. As such knowledge as this can only be gained by a patient scientific study of large numbers of children of all classes, the establishment of a psychophysical laboratory by the National Government would be a great public benefit.

Mr. Macdonald, in the book which he has published recently advocating this scheme, relates many instructive and useful facts bearing on child study. He says that all boys and girls show the same percentage of brightness, but the girls have 5 per cent. less dulness, and so, in general, may be said to be a little brighter than the boys, but this may be due to the fact that girls reach maturity sooner than boys.

Children of American parentage are brighter than children of foreign parentage or children of foreign and American parentage. This seems to indicate that a mixture of nationalities is not always advantageous in its effect upon the offspring.

Children of the non-laboring classes are mentally superior to those of the laboring classes, indicating that the advantages of good social conditions are favorable to mental brightness. On the other hand, boys of the non-laboring classes show a much higher percentage of sickness and nervousness than boys of the laboring classes, indicating that easier social surroundings are not always conducive to health.

While almost all children, boys especially, are lazy at times, there are, nevertheless, a number of children who seem to be chronically lazy. Dull boys have the highest percentage of laziness. Comparing all boys and girls the boys were found to be more lazy by far than the girls. Again, boys are much more unruly than girls, and, in general, show a much higher percentage of defects than girls. A general conclusion as to all children with abnormalities is, that they are inferior not only in mental ability, but in weight, height, and circumference of head to normal children.

The above data were founded upon investigations of 20,000 Washington school children, by Mr. Macdonald. The writer expresses his conviction that a thorough study of any human being cannot be made without instruments of precision. Such an investigation of living man is one of the most recent tendencies of science. Instruments of precision have been employed more extensively, perhaps, in the study of the abnormal, as illustrated in criminology, but it is time, thinks Mr. Macdonald, that they were used in the investigation of normal man.

Among the many interesting facts mentioned is that referring to the influence of poverty on nutrition. According to Leharzik, growth is regular,

and all deviation tends to produce disease, as disease also produces deviation. A large head is frequently accompanied by a contracted chest; here mental action may be slow—probably from deficient supply of purified blood. Boys of small frames often have rather large heads, and are deficient in repose of character. City-bred children are usually more vivacious, but have less power of endurance than children reared in the country.

In the report of the Anthropometric Committee of the British Association for the Advancement of Science are given the results of observations in over 50,000 individuals. It is shown how the growth lessens as we go lower in the social scale; there is a difference of five inches in average statures between the best and worst nurtured classes in the community.

Dr. Paul Hasse, in 1880, measured 2,806 children in Gohlis-Leipzig. Comparing the poor with the well-to-do classes, the results showed that for boys of the same age the height varied from 0.7 to 4 cm. in favor of the well-to-do classes; for girls it varied from 1.7 to 4.1 cm. in favor of the well-to-do. The children of the well-to-do classes excel, also, in weight, for the same age; for boys the excess runs from 0.3 to 4.7 pounds; for girls from 1.6 to 4.6 pounds. In general, the difference between the classes is not so great as in other places, as in Freiburg and Turin, except in Boston, where the difference between the classes is less marked.

Hasse also gives data concerning the weak or defective children, who generally cannot attend school regularly. Such children are usually abnormally developed, or have some chronic ailment. In the primary schools 9 per cent. belonged to this class. A striking fact is this, that in many cases these children in certain years were over normal—that is, were taller and heavier than other children.

This suggests, says the author, "that there is a certain normal relation between mental and physical development, the finding of which is one of the aims of anthropometry."

It is only within the past few years that the study of man upon scientific lines has been seriously considered as possessing any practical value. In Europe, and especially in Italy, anthropometry has come to be looked upon with consideration by all the leading scientists, and although occasionally one hears criticism of the method, yet upon the whole public opinion is veering round in favor of the new science.

There are always some individuals who distrust and sneer at new things, upon general principles, but the value of the study of man is now acknowledged on all sides.

Mr. Macdonald says, with much truth, that the day has come when opinion, theory, or speculation must give way to first hand knowledge. The value of opinion depends upon such knowledge, an ounce of which is worth a pound of theory. A great deal of the opposition to investigations of this nature also may be due to the mistaken idea that psychophysical studies tend to materialism or are liable to undermine morality and religion, but such unfounded opposition is gradually ceasing, and where it does exist it is due either to ignorance or to mistakes that may often occur in the introduction of new methods.

ANTISEPTICS IN THE TREATMENT OF DYSPEPSIA.

Dyspepsia is the most common complaint to which the human race is subject, or at least it is the affliction which most frequently attacks that large portion of the people of the earth termed civilized. Indeed, affections of the digestive tract are one of the outcomes of civilization, a penalty which we have to pay for our artificial mode of living. Persons living in a primitive manner are not even aware that they have a digestion. Rich food, overeating and drinking, late hours, insufficient exercise, a sedentary life spent in badly-ventilated houses fully account for the trials of the civilized stomach, and for the large number of unhealthy-looking, weazened, spiritless individuals, who may be seen on any day in the streets of the present time town.

Dyspepsia is without a doubt the disease of the age, and especially the one which has its headquarters in the United States. The fact, too, must be borne in mind that there is no malady, even of the gravest nature, which causes more distress to mind and body than obstinate and long continued dyspepsia. This functional complaint often does more to render life a burden than many of the most deadly diseases.

The remedial agents used in the treatment of dyspepsia are many and varied. The dyspeptic is frequently dosed by medical men with drugs by the score, while he is the principal supporter of quacks and patent medicine manufacturers and vendors. Of course, the sane treatment of ordinary dyspepsia is by means of careful dieting, exercise, fresh air, and a thorough application of all hygienic measures.

Dr. Guthrie Rankin writes in the *British Medical Journal* on dyspepsia and its general treatment, and particularly of the use of antiseptics as therapeutic agents. He says in part: "As regards medicinal treatment, limits of space will not permit any full discussion of the vast multitude of drugs that have been recommended and employed for the alleviation of dyspeptic troubles. I desire only to direct attention to those which, by a long process of elimination, I have personally found most useful, and particularly to point out the special value which I believe attaches to their combination with antiseptics."

Referring to atonic dyspepsia, the writer says: "In the large majority of cases of this form of indigestion, early and marked relief is afforded by the administration of a combination of dilute hydrochloric acid, pure carbolic acid, strychnine, and ginger. The hydrochloric acid supplies what is deficient in the scanty and feeble gastric secretion; the carbolic acid counteracts the tendency to excessive fermentation; the strychnine stimulates the muscular activity of the stomach walls, and the ginger acts as a carminative, and also as a stimulant to salivary secretion. The addition of a small quantity of glycerin to the mixture renders it more palatable."

With regard to therapeutic remedies for acid dyspepsia, Dr. Rankin says: "Alkalies are specially indicated in this form of indigestion. They should be administered two or three hours after food, and are, in my experience, increased in efficacy if combined with an antiseptic. Of all alkalies none is more useful than bismuth. The carbonate is probably the most suitable preparation of the drug. It should be given in 30 or 40 gr. doses, and may be associated with salol in 10 gr. doses, with sodium

sulphocarbolate in 15 gr. doses, or with carbolic acid in 2 gr. doses. To these may be added strychnine, ginger, or ammonia, together with a suitable quantity of one of the pharmacopœial solutions of morphine, if there be much pain. In most cases the following formula may be depended on: Bismuth carbonate, 30 grs.; aromatic spirits of ammonia, half a drachm; carbolic acid, 2 grs.; solution of strychnine, 5 minims, with, in addition, if there be pain, solution of morphine, 10 mimims. Bismuth salicylate is another valuable preparation, which contains within itself antiseptic and alkaline properties, and may be given in doses of from 10 to 15 grs. When the acidity, despite this bismuth mixture, gains the upper hand, temporary relief will always be obtained by sipping a wineglassful of very hot water in which 20 or 40 grs. of sodium bicarbonate have been dissolved."

With respect to drugs in the treatment of nervous dyspepsia, the author says: "It is desirable in all cases belonging to this variety of dyspepsia to increase the quantity and variety of food as rapidly as possible, and it is especially necessary to get the patient to take as much fat in a digestible form as he is able to assimilate. The stomach discomfort depends upon nerve exhaustion, and is only a local manifestation of a constitutional state, which will not benefit from the routine treatment by acid or alkalies. In this, however, as in other forms of indigestion, fermentative processes play a considerable part in the causation of the patient's discomfort, and again, therefore, antiseptics ought to be administered as part of the medication. Dr. Rankin thinks that the most reliable for affording relief are zinc valerianate and arsenic."

That antiseptics should have a good effect upon those suffering from dyspepsia would seem to be justified by the facts of the case. Nervous dyspepsia is the form of the complaint from which the greater number of dyspeptics in this country suffer, and the advice given by Dr. Rankin that persons in this condition should eat well and vary their diet is excellent.

After all, diet is the chief factor in curing dyspepsia, although some drugs are great aids in effecting this object.

FORMALIN IN SEPTICÆMIA.

The recovery of a woman suffering from puerperal septicæmia, and whose life was hanging by a thread, has attracted much attention in medical circles recently. The patient, a negress, was admitted to Bellevue Hospital on December 25, and had given birth to a child eight days before. When admitted she had a temperature of over 104°, and within twenty-four hours this had risen to over 107°. A bacteriological examination of the blood confirmed the diagnosis of blood-poisoning, and, in fact, the case was looked upon as hopeless. Dr. Barrows, the assistant to Dr. Polk in the obstetrical ward, then asked if he might try an injection of formalin solution, and, upon the request being granted, made an intravenous injection of 500 cubic centimeters of a solution of 1 to 5,000 of formalin into the woman's right arm. The effect of this treatment appears to have been magical. Soon after the injection the temperature began to fall, and by the next day was 101°. On the second and third days after the injection, however, the temperature again began to rise, and a bacteriological examination showing that the blood still contained streptococci, formalin solution was injected a second time, but into the veins of the left arm, the quantity being increased to 750 cubic centimeters, when the temperature fell and the pulse dropped to normal within a few hours.

Since the above case was thus treated, a white woman suffering from septicæmia at the Hahnemann Hospital has been subjected to the same methods, and with equally satisfactory results. Formalin has been used for some time in the treatment of tuberculosis. Its active principle, formaldehyde gas, has been administered by inhalation to consumptive patients, but, owing to the harm done to the lung tissue by the fumes, the outcome has been disappointing. The strong chemical agent has acted in the cases noted above with neutralizing effect, its antitoxic properties have antagonized the poison of the blood to such a degree that its harmful action has been arrested, and the opportunity given for the recuperative powers of the system to have fair play.

The discovery of Dr. Barrow—if it stands the test of time—is assuredly of the highest value, indeed, if formalin fulfils the expectations formed of its germicidal effect in cases of septicæmia, its first use will mark an epoch in the history of medicine. At the same time it is well that the matter should be regarded from a conservative standpoint, and that hopes which may prove elusive should not be raised until a number of patients suffering from septicæmia have been treated successfully by the method. The initial experiments have been most encouraging, and incline one to the belief that at length a specific for blood-poisoning may come within the bounds of practical medicine.

The Yeast Treatment of Gonorrhœa in Women.

A curious and interesting revival into the arena of modern practical therapeutics of a treatment practised by Hippocrates and Dioscorides, is afforded by the above mode of therapy. Rediscovered by Landau in 1899, the method has recently received at the hands of Otto Abraham a critical overhauling. This author studied the subject, apparently with great care, from the chemical, bacteriological, and clinical standpoints. and,as far as we can judge from his careful detailed experiences, in the *Monatsschrift für Geburtshülfe und Gynäkologie* for December, 1902, it would seem as though the yeast treatment might not unlikely take a permanent place in therapeutics. Chemically, after numerous experiments, Abraham found the most active form of yeast to be the living cells plus asparagin. Bacteriologically, too, he found that this combination exerted the maximum effect in destroying gonococci in cultures of gonococcal vaginal mucus. Clinically, 40 patients were examined who presented the following conditions: Acute vulvitis, 9 times; urethritis, 3; Bartholinitis, 3; colpitis, 10; erosions of portio, 12; endometritis cervicis blenorrhoica, 34; and endometritis corporis blenorrhoica, 3. Vulvitis, colpitis, and erosions were the conditions most rapidly influenced; after one or two days the pruritus and burning lessened, the flow became clearer and lost its purulent character, and after a few days vanished. Even dollar-sized erosions healed in four to eight days on an average. Two cases of Bartholinitis required incision; the other subsided without it. Urethritis was entirely unin-

fluenced. Of the thirty-four cases of endometritis cervicis, thirty were completely cured within five to twenty-three days. The flow shortly became clearer and thinner; in the first days it increased in quantity, then rapidly subsided. Of the three cases of endometritis corporis one was entirely cured, which shows the possibility of influencing the body of the uterus from the vagina, at least with yeast which may, so to speak, multiply its way in. Of the six refractory cases of endometritis (cervicis four, corporis two), three were afterward cured by the insertion of a "pencil" consisting of yeast, asparagin, and gelatin, into the cervical canal. In all the cases, even those last mentioned, the treatment was effected without any unpleasant results, or any untoward reaction; only two patients complaining of slight itching during the first days. The patients were examined for gonococci before, during, and after treatment. Of the forty, twenty-eight showed gonococci before treatment; after it the most careful search failed to detect any. Other cocci and bacteria in the vaginal mucus, staining with Gram's method, decreased in number and colorability. The gonococcicide action of the yeast is chemical, and due to an enzyme. The yeast cells do not live long in the vagina; three days after the discontinuance of treatment they could no longer be found. Whereas former observers have used the yeast by injections of fluids containing it, Abraham introduced a decided improvement by employing a suppository of yeast, asparagin, and gelatin; and in the case of cervix uteri, a "pencil" of the same ingredients, but of firmer consistence. A suppository is inserted at night and the napkin put on, and in the morning the vagina is syringed out.

Watercress and Cancer.

Cancer has been attributed at one time or another to the consumption of tomatoes, salt; arsenic, or rather, to write accurately, it has been suggested that these articles might be contributing causes. A correspondent, a short time ago, wrote to the London *Daily Chronicle* stating his belief that cancer might be caused by eating watercress, because he had found fresh-water shrimps and some worms in a specimen of this vegetable which he had purchased.

The letter to the *Chronicle* has given rise to a somewhat animated discussion, and among others who took up the matter was Mr. George R. Sims, the well-known writer who contributed to his own journal, *The Referee*, some well-matured thoughts anent the subject.

Dr. Andrew Wilson then entered the lists, and in both journals ridiculed the idea that there could possibly be any connection between watercress and cancer. Dr. Wilson truly says: "Some people do not realize what scientific proof implies and means. To suggest even a relationship between cancer and watercress, you would require to have a series of cases in which cancer followed the continuous consumption of the plant, and then you would require to eliminate all other causes. These 'scares' are the annoyance of scientific minds. I hardly know how many I have done my best so explode—including the idea that the healthful tomato can cause cancer. We are busy searching out the exact cause of the disease. Till that difficult task is accomplished you may advise your readers to treat with scorn all such suggestions as those I have mentioned." Dr. Wilson is certainly perfectly right to advise the public not to be led away by senseless scares concerning the cause of cancer, or of any other disease. But at the same time this is by no means the first occasion on which raw vegetables, which would comprise watercress, have been laid under suspicion as a possible cause of cancer. Some of the most eminent German investigators have given as their opinion that there may be some relationship between uncleanly raw vegetables and the disease. If it be granted that cancer is of parasitic origin, then might not the germ be taken into the system by means of eating raw vegtables.

Dr. Lyons of Buffalo, some time ago, made investigations into the relative frequency of cancer among the different nationalities of that city, and found that the malady was most frequent among the German population, notorious for consuming uncooked vegetables in large quantities. Of course scientific proofs are wanting to substantiate the theory, and that vegetable-eaters in Buffalo are more subject to cancer than the rest of its citizens may be nothing more than a coincidence. Nevertheless, if such were found to be the case in other parts of the world, a strong *a priori* argument would be established that there is a decided relationship between cancer and uncleanly raw vegetables.

The Outlook for Consumptives.

Dr. Robin of the French Academy of Science delivered at the Sorbonne, on January 7, a lecture which has created a sensation among all classes of society in France. Dr. Robin—the pith of whose remarks is given in the New York *Tribune* of January 11—is reported to have said that all that has so far been accomplished in the great fight against tuberculosis has been in vain, and that medical science and philanthropy have started on altogether the wrong tack. Dr. Robin does not hesitate to assert, and his position is supported by data which seemed irrefutable to such high authorities as Brouardel, Grancher, and Landouzy of the Paris Faculty of Medicine, that tuberculosis when once firmly established in the system is practically incurable. The only efficacious way to fight tuberculosis is, said the lecturer, by preventive measures.

The *Tribune* report proceeds as follows: "The discoveries just made by Dr. Robin and his colleague, Maurice Binet, enable the stage of predisposition to tuberculosis to be determined with mathematical accuracy. It is to this preliminary stage of tuberculosis that all efforts should be directed, the absolute remedy or preventive being easily attained by the air cure, by abstention from alcohol, and by complete mental and physical rest. Dr. Robin maintains that the sanatoriums, upon which millions have been uselessly expended, are, from a financial point of view, impracticable, and therapeutically simply chimerical. Dr. Robin supports his argument on the financial head by pointing out that, supposing only one hundred thousand beds were provided for the half million persons suffering from tuberculosis in France, and each bed cost $1,000 for initial endowment, we have at once $100,000,000 needed at the very outset, without counting incidental expenses."

The views of the well-known French authority are by no means novel, nor are they confined to himself and his followers. There are many medical men in every country of the world who believe that after a certain stage pulmonary tuberculosis is incurable. The disease may be arrested for a time and its victim benefited by fresh air and suitable diet, but if the malady has gained a firm foothold in the lungs the case is—in the opinion of probably the majority of physicians—practically hopeless—that again prevention is assuredly the means whereby consumption will be extirpated, if it ever is extirpated, is no

new doctrine. By providing the working classes with large well-ventilated and hygienic dwelling houses, more will be done to check the spread of tuberculosis than by any other methods.

Pulmonary tuberculosis is, however, curable in its early stages, and it is those who are thus afflicted who benefit from sanatorium treatment, and for whom these institutions are really needed. The assertion made by Dr. Robin that sanatoriums are useless, because it would cost too much to erect sufficient of these to accommodate all consumptives will not bear dissection. Even if but a fifth or sixth part of the consumptives could have the advantage of sanatorium treatment, it would be for their good and for the gain of the community at large, because in crowded districts the disease is spread through close personal contact.

The methods of prevention of pulmonary tuberculosis are these: Improving the conditions of life everywhere, and especially in cities. Early diagnosis of the disease, in order that the sufferer may undergo curative treatment under the most favorable auspices, and that as a source of spreading infection he may be removed to a place where he will be no menace to his fellow creatures.

Degree of Doctor of Public Health.

The memory of the practitioner of medicine who has pursued his professional labors for the past thirty or forty years need not be particularly acute to recall the tremendous strides which have been made in medicine within his recollection. "Stupendous" is an apt term with which to typify this progress. Nor has the advance been limited to any one branch of the subject, but all have partaken of the change. A specialist in 1860 was a *rara avis*, a pathologist then dealt in fields which were as fertile with expectancy as they were barren of established facts; a chemist had a knowledge of metallurgy as first title to his ability and as prior right to his appellation; a successful teacher at a medical school was recognized primarily by the extent of his practice. How changed to-day! In his individual capacity the citizen has derived the great benefits which have followed in the wake of the changed and improved conditions, but has the general public in its entirety reaped the reward which should ensue by reason of advanced and advancing knowledge of medicine and its allied branches? We fear not, and it rests with the profession to so alter the status of affairs that the full meed of benefit should accrue to the general public. The hygienists and the sanitarians who fill our public offices, as such, are, as a rule, men who have not been properly fitted for their vocation. The field of medicine is now so vast that no one human mind can encompass its various truths. Specialists are so largely in evidence in medicine to-day, because of the immensity of the proposition which stares him in the face who would acquire it all. Just as the best colleges to-day select as chemists and physiologists and bacteriologists, and many other specialists, men who devote themselves exclusively to these given fields and to the exclusion of the practice of medicine, so should graduated and licensed physicians be educated to fill the commanding posts of health officers—those who have been trained and educated with this purpose solely in view. Our medical schools should have courses, post-graduate, devoted exclusively to instruction in sanitation and hygiene, there to educate men who, when proficient therein, should after from two to three years of graduated study be given the additional degree of Doctor of Public Health. None others should be eligible to the position of Health Officer, and their remuneration should be such as to make them independent of income derived from other medical work or practice. In this manner will the public derive the full benefit of the increased knowledge in these subjects to which it is entitled. To-day the politician decides who shall thus serve the public and how often does it happen that a "pull" lands in such office the one who of all those applying is least capable of serving.the best interests of the community. By the means proposed the public, knowing otherwise, would demand a competent man. We would suggest that the Regents of the University of the State of New York announce the recognition of this proposed title, and that a test examination be offered the profession next year, prepared by men competent to act as a board of examiners for those desirous of being Doctors of Public Health. In the meantime the Legislature should specifically authorize the Regents to confer this title.

Successful Transplantation of Ovaries.

No subject opens wider vistas in experimental physiology than this. In the *Monatsschrift für Geburtshülfe und Gynäkologie* for December, 1902, Walther Schultz gives his results and a full résumé of previous work. So far this has not touched the wider anatomical, physiological, and psychological questions (whether castrated males with implanted ovaries develop the female form of pelvis, show preference for males, etc.), but has related only to the possibility of success in transplanting, and the changes occurring in the transplanted tissues. The possibility of transplantation is now demonstrated beyond question. Both in young and in almost grown animals, the ovaries become attached in their new position, whether this be the peritoneal cavity of the same female, of another female, or of a male, of the same breed or of a female of a different breed. Schultz's main conclusions are: on other females of the same breed, transplanted ovaries of mammals can give off eggs and form corpora lutea; on males of the same breed, such ovaries can develop ripe eggs up to forty-two days, and show such after 117 days; on females of other breeds such ovaries exhibit, in the first eight days, no difference from ovaries transplanted on females of the same breed; the mode of healing and development corresponds in the animals investigated to the phenomena described by Ribbert; and, in ovaries transplanted on to males, eggs can be demonstrated in the root, and tube-formed processes crowding from the germinal epithelium downward into the tunica albuginea. At the same time, according to Ribbert and Schultz, changes take place which at least simulate the embryonic condition—mitosis appears in the cells of the germinal epithelium, and from it root-like, or tube-like processes grow downward into the tunica albuginea. In these processes Schultz was able to demonstrate eggs. The transplanted ovarian tissue appears not to be injuriously influenced either by the blood of the male or by anything (secretion or other influence) from the testicles; at least no such influence was noted in the somewhat short time covered by the experiments. Transplantation does not operate to produce any unusually rapid growth in ovarian tissue, as might possibly be expected, considering that it is tissue freed from its normal connections. The author suggests that it is imperative that this subject be followed up by such experiments as implantation of ovaries in a female of another breed whose ovaries have been previously removed, and that breeding experiments be then carried out with the male of that breed. And we might mention many other experiments which crowd on us, but they are too obvious.

News of the Week.

The Plague.—The national convention of delegates from the State Boards of Health of Connecticut, Colorado, Texas, Louisiana, Minnesota, Maryland, Illinois, New York, and Pennsylvania, called to consider the danger threatened by the possible introduction of the bubonic plague into the United States, assembled in Washington on Monday, January 19. Each State was represented by one delegate. The slow course of the disease in San Francisco continues unchanged. The port of Panama has declared a quarantine against steamers from that city. Dr. E. Licéaga, President of the National Board of Health of Mexico, reports that during the month ending January 15 there were 116 deaths from bubonic plague at Mazatlan. No report has been received from Fusenada, Lower California, since December 25, but that up to that time only two deaths from the plague had occurred there. It is asserted that the plague was taken to Mazatlan from San Francisco, and not from China, as was originally reported. It is reported from Durban that there have been seventeen deaths from the plague in Natal. In addition there were on January 20 thirty-five cases known to the authorities, one being in the person of a European.

Sale of the Florida Quarantine Stations.—The United States Treasury Department has purchased from Florida the State's quarantine stations at Pensacola, Charlotte Harbor, Fernandina, Miami, and Mayport, at a cost of $32,000. This sale was in obedience to a joint resolution of the Florida Legislature of 1901, after an appraisement. The Federal Government took over the quarantine system in July, 1901, and has been operating it since. but the title to the property remained in the possession of the State.

Superintendent of the Health Department Hospitals.—Health Commissioner Lederle of New York City has appointed Dr. George Taylor Stewart, ex-Superintendent of Bellevue Hospital, to the position of Superintendent of Hospitals of the Board of Health, with a salary of $2,500 a year. In his new position Dr. Stewart will be in charge of the Riverside, Willard Parker, the Reception Hospital, and the Kingston Hospital in Brooklyn.

Closure of a Hospital.—The Williamsburg Hospital closed its doors last week because of a lack of funds and the high price of coal and foodstuffs. The institution was located at Bedford avenue and South Third street, and the charity patients were yesterday transferred to the Eastern District Hospital, and the private patients to their homes. The ambulance was sold to the Bushwick Central Dispensary. The hospital was established as the Brooklyn Throat Hospital, and in 1895 the name was changed to the Williamsburg Hospital.

A New Eye, Ear, and Throat Hospital in Philadelphia.—The will of Dr. Bushrod James, which was probated last week, devises to the city of Philadelphia $55,000, several pieces of real estate in the city, and several lots at Island Beach, N. J., for the purpose of establishing in Philadelphia a free hospital for the treatment of diseases of the eye, ear, throat, and lungs. The will directs that the $55,000 be invested as an endowment fund. The proposed hospital is to be called the Washington James Eye and Ear Institute.

Bequests to Charitable Institutions.—Under the will of the late Isaac T. Carpenter, each of the following institutions will receive $1,000: The Woman's Hospital, New York Society for the Relief of Ruptured and Crippled, German Hospital and Dispensary, New York Eye and Ear Infirmary, Mount Sinai Hospital, New York Infirmary for Women and Children, New York Homœopathic Infirmary for Women in the City of New York, Home for Incurables, and the Nursery and Child's Hospital. In addition to these hospitals, some twenty asylums, homes for the aged, and aid associations receive equal amounts.

The Hospital Saturday and Sunday Collections have been unusually large this year, and from the returns already received it is believed that the total amount will far exceed that of any previous year. The collection last year amounted to $80,000.

Governor Odell and the State Hospitals.—The tenth annual report of the State Charities Aid Association to the State Commission in Lunacy, of which advance sheets have just been issued, reviews at considerable length the legislation of the year 1902 affecting the State Hospitals. The legislation carried out the recommendations of the Governor, to which the Charities Aid Association was opposed. The new powers conferred on the Governor are summarized, and the conclusion is reached that "the welfare of the insane is now virtually in the hands of the Governor, and it is he who must be held not only ultimately but, in large measure, directly responsible for this huge department of the State's service."

Typhoid Fever and Smallpox in Philadelphia.—There were reported to the Philadelphia Board of Health 217 cases of typhoid fever for the week ended January 10; there were reported 144 cases for the week ended January 3; and a total of 906 cases for the nine weeks ended January 10. The great increase in this number has been coincident with a low water-supply, the disease being most prevalent in parts of the city in which the water is supplied by direct pumpage. An increased number of cases of smallpox was reported to the Board of Health for the week ended January 10, namely, thirty-three, as compared with fifteen for the preceding week. There was but one death from the disease in the two weeks.

Philadelphia Pediatric Society.—At a stated meeting, held January 13, Dr. Theodore Le Boutillier presented a girl of nine years with an aneurysm of the transverse portion of the aortic arch. The child had had an attack of whooping-cough at the age of nine days and a second attack at the age of four years, and to the effects of which the conditions present were attributed. The physical signs comprised abnormal pulsation, at times of an expansile character, over the upper portion of the sternum, with thrill on palpation, an increased area of dulness on percussion, a loud blowing murmur with the first sound of the heart an accentuation of the second sound. The symptoms were disproportionately slight. Dr. Samuel McClintock Hamill delivered the Annual Address of the Retiring President. After first reviewing the work of the society for the preceding year he delivered a most interesting and appreciative memoir of the late Dr. Frederick A. Packard, one of the original and also one of the most active members of the society and a former president.

Philadelphia County Medical Society.—At a stated meeting, held January 14, a resolution was adopted endorsing a bill presented to the Congress of the United States for the payment to the widow of the late Major Walter Reed, Surgeon, U. S. A., of a pension equivalent in amount to the pay received by Dr. Reed at the time of his death. Dr. Mordecai Price reported a case of Cæsarean section in a woman who had been in labor for forty-eight hours, delivery being prevented by a contracted pelvis. The opera-

tion was performed in order to save the life of the mother, as the child was already dead. The patient made a good recovery. Dr. John V. Shoemaker presented a communication entitled "A Clinical Description of a Case of Tubercular Leprosy." The patient had been thought to be suffering from mycosis fungoides, but the clinical manifestations were suggestive of leprosy, and examination of a bit of affected tissue and of the blood disclosed the presence of lepra-bacilli. Dr. L. Napoleon Boston read a paper entitled "The Lepra-bacillus in the Circulating Blood," in which he described the findings in the case reported. Dr. Judson Daland read a paper entitled "Observations upon Leprosy Occurring in Japan, Iceland, and Norway." The discussion was participated in by Drs. H. W. Stelwagon, M. B. Hartzell, Jay F. Schamberg, and Matthew Woods.

The Enno-Sander Prize of the Association of Military Surgeons of the United States.—The announcement is made that this prize for 1903 will be awarded to the author of the best essay on "The Differential Diagnosis of Typhoid Fever in Its Earliest Stages." Competition is open to all persons eligible to active or associate membership in this association. The first prize consists of a gold medal of the value of $100; the essayist who secures first honorable mention will receive a life membership in the association. The board of award will consist of Dr. Austin Flint of New York, Col. Calvin DeWitt of the Army, and Prof. Victor C. Vaughan of Ann Arbor. Full information concerning the contest may be obtained from Maj. James Evelyn Pilcher, Carlisle, Pa., the Secretary of the association.

Dr. W. B. Whierry, associate in bacteriology at the University of Chicago, has received an appointment to the post of bacteriologist in the government laboratories at Manila, P. I.

Medical Society of the Missouri Valley.—The semi-annual meeting of this society will be held at Council Bluffs, Iowa., on Thursday and Friday, March 19 and 20, under the presidency of Dr. J. M. Barstow of Council Bluffs. The feature of the first day will be a symposium on "Syphilis," to which contributions have been promised by Drs. R. C. Moore, A. C. Stokes, and F. E. Coulter. On the second day will be a symposium on "Typhoid Fever," the names of the contributors to which have not yet been announced. Membership in this association includes practitioners in Iowa, Nebraska, Missouri, Kansas, North Dakota, and South Dakota. Council Bluffs is the birthplace of the society, and it is hoped that the meeting will, on this account, be largely attended The secretary of the association is Dr. Charles Wood Fassett of St. Joseph Mo.

Missouri State Medical Association.—The annual meeting of this association will be held at Excelsior Springs April 21, 22, and 23, 1903, instead of May 19, 20, and 21, 1903, as previously announced.

The King's Tuberculosis Sanatorium.—The issue of the *Lancet* of January 3, 1903, is devoted to a presentation of the three prize essays on the construction of King Edward's Sanatorium for Tuberculosis. The essays are printed in full, and are accompanied by carefully made plans drawn by the architects associated with the medical essayists. The first prize, of the value of £500, was awarded to Dr. Arthur Latham of London, with whom was associated, as architect, Mr. William West of London. The second prize, of the value of £200, was awarded to Dr. F. J. Wethered of London, with whom were associated, as architects, Messrs. Law & Allen of London. The third prize was given to Dr. E. C. Morland of Croydon, with whom was associated, as architect, Mr. G. Morland of Croydon. Honorable mention was also made for essays of great excellence of Drs. P. S. Hichens of Northampton, Turban of Davos, Jane Walker of London, and J. P. Wills of Bexhill.

Academy of Medicine of Toledo.—At the annual meeting of the Academy of Medicine of Toledo and Lucas County, held this month, the following officers were elected: *President*, Dr. Julius H. Jacobson; *Vice-President*, Dr. S. S. Thorn; *Secretary*, Dr. H. E. Smead; *Financial Secretary*, Dr. Charles P. Wagar; *Treasurer*, Dr. W. W. Grube; *Board of Censors*, Drs. Wm. H. Eisher, O. Hasencamp, W. J. Gillette, John A. Wright, and S. W. Beckwith; *Members of the Library Board*, Drs. S. S. Thorn, Harrison Hathaway, W. J. Gillette, Park L. Myers, and A. L. Steinfeld; *Committee on Legislation and Public Health*, Drs. W. C. Chapman, C. L. Van Pelt, and W. G. Dice.

The First Surgical Division of Bellevue Hospital.—Dr. R. W. Taylor has been appointed consulting surgeon, Dr. J. R. Hayden attending surgeon, and Dr. J. R. Whiting assistant attending surgeon, Genitourinary Department, at Bellevue Hospital.

Legal Registration of Nurses.—One of the measures likely to be presented early in the legislative session at Albany has for its purpose the registration and licensing of trained nurses. This proposed legislation had its birth in the city of Rochester, and has received the encouragement and support of prominent members of the medical profession. A board of five examiners, appointed from among names presented to the Regents by the State Association of Nurses, is, under regents' rules, to conduct examinations of all eligibles, the successful ones to receive license as *registered nurses*. This measure will not attempt to restrict others not so licensed from following this vocation, but will debar them from using the title "Registered Nurse," just as at present none other than persons so licensed by the regents are permitted to advertise themselves as "certified accountants." We know of no objection to this proposed law, and if, as it is claimed, it will enable the public and the profession to differentiate the experienced and the inexperienced nurses, the bill deserves to pass.

Pathological Society of Philadelphia.—At a stated meeting, held December 18, Dr. T. S. Githens reported a fatal case of anthracosis. The patient was a young man employed as a barber, who had formerly worked in the coal mines and presented symptoms suggestive of pulmonary tuberculosis, although tubercle bacilli were not found in the sputum. Death resulted from exhaustion, and post-mortem examination disclosed fibrosis of the lungs with deposits of carbonaceous material in the interstitial tissue, in the alveolar and bronchial cells, and in the lymphatic glands, and obliteration of the pleural cavities. Dr. J. K. Walker exhibited a gallstone of unusual size, which he had removed by operation. The presence of the calculus in the gall-bladder being suspected from the symptoms and physical signs, that viscus was exposed and incised and the stone removed. The foreign body measured about 9 by 6 cm., and weighed 550 gms. Dr. S. Rhoads showed a bronchial cast expectorated by a patient suffering from pulmonary tuberculosis, and referred to a number of similar cases recorded in the literature. Dr. A. A. Eshner reported a case of polyarthritis complicated by choreiform symptoms and vegetative endocarditis. The patient was a young man, seventeen years old, who suffered from pain, swelling and stiffness in numerous joints, with elevation of temperature and acceleration of pulse and respiration. Under observation the patient became

restless and emotional, and he finally developed rather violent, involuntary, incoordinate, jerky movements. Death took place as result of exhaustion. Post-mortem examination disclosed the presence of vegetations on the leaflets of the aortic and mitral valves, but no lesion of the central nervous system was found on macroscopic and microscopic study. Dr. Eshner entered upon a brief discussion of the etiology of the various forms of arthritis, including acute rheumatism, and of that of chorea, and he pointed out the relations existing between these several disorders.

Obituary Notes.—Dr. Susan R. Pray died at her home in Brooklyn on January 14, after an illness of two months' duration. She was born in Brooklyn forty-five years ago, and was a graduate of the Woman's Medical College of the New York Infirmary in the class of 1882. After graduation she practised in Brooklyn for three years, and then went to China as a missionary for the Woman's Foreign Mission Board of the Methodist Episcopal Church. She was in China two years, when her health failed, and she had to return to Brooklyn. She was a member of the American Medical Association, of the American Public Health Association, and of the New York State Medical Association. She was for thirteen years connected with the Health Board of Brooklyn.

Dr. George W. Harding died at Ahmednagar, India, on January 13, of septicæmia. He was born in India, the son of the late Rev. Charles Harding, a missionary of the American Board at Sholapur. He was a graduate of Oberlin College and of the Rush Medical College. Dr. Harding and his wife joined the Marathi mission two years ago.

Dr. Robert H. Goldsmith, aged seventy years, died suddenly of heart disease in Baltimore on January 14. He was a graduate of the University of Maryland School of Medicine in 1852. He was not only a practitioner of high standing, but was noted as well for his philanthropy, being connected with numerous charitable institutions.

Dr. Frederick J. Bancroft of Denver died on January 17 in San Diego, Cal., from heart disease. He was born in Connecticut in 1834, and was graduated from the Medical Department of the University of Buffalo in 1861. He was well known as a railway surgeon of wide experience, and had also made many contributions to the literature of climatology.

Dr. James McCullough of Watertown, N. Y., died of apoplexy on January 13, at the age of forty-eight years. He was a graduate of the New York University Medical College in 1880.

Dr. Hilbert B. Tingley, a prominent physician in the Borough of Queens, was killed on January 14 by falling under the railroad cars, while attempting to board a moving train. He was forty-five years old, and was a graduate of the Medical Department of the University of Baltimore in 1889. He had practised at Rockaway Beach for many years, and was known as the poor man's doctor, because of his readiness to respond to charitable calls day or night without hope or expectation of a fee.

Dr. Jacob L. Heller died from pneumonia at Philadelphia on January 12, at the age of thirty-six years. He was a native of Roumania, came to this country in 1885, and was graduated from Jefferson Medical College in 1892.

Dr. Albert Waring Atwater of St. Regis Falls, N. Y., died at Burlington, Vt., on January 9. He was born in 1861, and was graduated from the University of Vermont Medical College in the class of 1885. He came from a line of physicians, his father and grandfather having passed their lives as practitioners of medicine in Burlington.

Correspondence.

FIRST EGYPTIAN CONGRESS OF MEDICINE.

(From Our Special Correspondent.)

(*Continued from page 108*)

Cairo, January 2, 1903.

The subject of ankylostomiasis aroused a much livelier and more real interest among the visitors than that of bilharziosis did. This is not to be wondered at, when it is recalled that the latter has a purely local (*i. e.* African) interest, whereas the former has a distribution which can now be truly called world-wide, and, as recent experience shows, must be remembered in seeking for the cause of obscure cases of anæmia, even in America and England.

Perhaps the most important contribution to the Section of Medicine was the demonstration given by Professor Looss, of the manner in which the ankylostoma larva enters the body. It will be remembered that last year Dr. Looss published the statement that this larva can certainly enter the body through the skin. He had himself become infected with the disease, by larvæ which entered through the skin of his hands; and in the case of a patient, upon whose leg water containing ankylostoma larvæ was placed a short time before the limb was amputated, the worms were afterward found in the hair follicles of the skin, and others below the skin in the subcutaneous tissues. The narration of these experiences failed to convince many scientists; so, in order to persuade these sceptics that skin infection does really take place, Professor Looss brought before the Congress still further proofs of his views. A native servant (who had been employed in the Kasr-el-Ainy Hospital for six years, and had been quite free from any suspicion of the disease), volunteered to submit himself to the test. For four weeks Dr. Looss, from time to time, examined this man's fæces for ankylostoma eggs in vain; he then applied to the skin of his arm some water containing ankylostoma larvæ; on the seventy-first day after this application a few (an average of two per specimen) ankylostoma eggs were found in the fæces, and the number of eggs has been increased at each examination up to the present moment (one month later), when the average number of eggs in each microscopic preparation has risen to thirteen.

Yet another experiment was made to demonstrate this mode of infection. Dr. Looss roughly clipped the hair on the side of a healthy dog's thorax, and loosely applied to this skin area (still covered with short hair) a mixture of fecal matter mixed with charcoal, in which larvæ of the ankylostoma worm of dogs had been bred. Nine days afterward all the symptoms of ankylostomiasis made their appearance, and on the following day the dog died. Post-mortem examination revealed the typical aspect of ankylostomiasis-anæmia, and in the intestine large numbers of young worms, which had reached just that state of development to be expected after being ten days in the body. This experiment was repeated on another healthy dog, with a result absolutely identical in every respect with that of the first. Professor Looss has thus been able not only thoroughly to convince himself that ankylostoma infection does take place through the skin, but has gathered together a mass of positive evidence which must convince every reasonable sceptic of the truth of his contention.

Dr. Looss is now conducting experiments which aim at reproducing as nearly as possible the natural conditions in which the ankylostoma-infection takes place. He applies to the feet (of healthy human volunteers) Nile mud containing the larvæ, with a view to the determination of the route taken by the parasite to reach the duodenum.

Major Gorgas of the United States Army Medical Corps gave an interesting account of the investigations carried on chiefly in Cuba, to elucidate the mode of transmission of yellow fever, and also of the means adopted to check the spread of this disease in tropical America, and especially in Havana.

Dr. Kartoulis (Alexandria) read a very interesting and important communication dealing with the etiology and treatment of tropical dysentery, and abscess of the liver. He discussed the differences between the endemic and epidemic forms of dysentery. The former occurs in the tropics, having been found in various parts of Africa, the East Indies, and the Asiatic Islands generally, in China, in South America, and in parts of the United States. It is always due to the presence of amœbæ—protozoons of the class of rhizopods. The epidemic form of dysentery is not confined to warm climates, but may occur in cold countries like Japan and parts of Europe; it also occurs in the Antilles. It is caused by the bacillus of shiga. In the subsequent discussion it was stated by Professor Chantemesse (Paris) that he and Widal discovered this bacillus (in the excreta of soldiers returned from Tonkin) in 1888 *i. e.* ten years before Shiga called attention to it in Japan

Recently, he had compared this organism with specimens derived from various countries (Germany, the United States, and France), which had been isolated by Kruse, Flexner, Pfuhl, and Duval, and found them to be identical. Professor Chantemesse candidly admitted the inconclusive nature of his early discovery of this bacillus as the cause of epidemic dysentery, which Shiga afterward demonstrated.

After describing his well-known experiments, in which he produced typical endemic dysentery in cats, by the injection of dysenteric stools containing the characteristic amœbæ, and failed to produce the disease by injecting dysenteric fæces containing only saprophytic amœbæ, Dr. Kartoulis discussed, at length, all the objections which have been urged against this mode of causation of the disease. To the satisfaction of all his hearers, he refuted, by means of reports of cases and experiments, all the statements of various writers purporting to disprove his view that tropical dysentery is not caused by the amœba of Kartoulis.

He expressed his emphatic belief that these "dysenteric amœbæ" are the sole cause of tropical or "amœbic" dysentery. Moreover, he found that tropical abscess of the liver is due, in 75 per cent. of the cases, to amœbic dysentery. Non-dysenteric abscess of the liver in tropical countries is due, in great part, to intestinal lesions, and only a small number of cases are pyæmic in origin. Alcohol and, more rarely, malaria give rise to an inflammatory hepatitis, which predisposes to suppuration without being the direct cause. The actual suppuration is, of course, due to pyogenic microbes.

After trying a great number of remedial measures, Dr. Kartoulis has finally adopted, as a routine measure for the treatment of tropical dysentery, and as a prophylaxis against abscess of the liver, abundant lavage of the intestine, with an aqueous solution of tannin (0.50 per cent.). The lavage is performed twice on the first day. Purgatives are of no importance.

Professor Chantemesse (Paris), in the subsequent discussion, said that the only important omission in Dr. Kartoulis's excellent report was his failure to mention his own (Kartoulis') great merit in discovering the undoubted cause of amœbic dysentery.

Dr. Voronoff (Cairo) discussed the surgical treatment of abscess of the liver. He advocated the necessity of a large resection of the ribs, suturing the pleura and peritoneum, and curettage of the abscess cavity. A lively discussion ensued as to the desirability of curetting the lining of the abscess, the followers of the French teaching advocating, and the Germans, especially Dr. Goebel (Alexandria), condemning this proceeding.

Professor Fornario (Cairo) read an exhaustive communication on malaria in Egypt, and also discussed many points of general clinical interest in this disease, more especially with reference to its influence on the heart, liver, and kidneys.

He came to the conclusion that, although malaria is common at Alexandria, the sea-coast, and fringing the Suez canal, it also occurs in other parts of Egypt—for instance, Cairo, Assuan, and the Delta. Between September, 1899, and December, 1901, he had seen sixty-six cases of malaria.

In Egypt, as in Europe, the disease presents itself in various forms. In Cairo the tropical form (tertian or quotidian) occurs almost exclusively; at Ismailia (Suez Canal) it is the simple tertian and quartan form.

Many cases occur with all the symptoms of malaria, and react to quinine, and yet examination of the blood has failed to demonstrate the plasmodia.

In the malarial fever of Egypt it often happens that the enlargement of the spleen is very slight, or even not present. On the contrary the liver undergoes great enlargement, and hence the differential diagnosis of abscess of the liver and malarial fever sometimes crops up.

The kidneys are very often affected, but the trouble is usually not serious.

In addition to displacements of the heart, caused by hepatic and splenic enlargements, dilatation of the heart, in malaria, is much commoner (not only in Egypt, but also in Italy) than is usually supposed, and may give rise to serious complications.

Professor Tessier (Lyons) gave a full account of the pathological anatomy and means of diagnosis of malarial nephritis. It especially attacks the epithelium of the tubules, and in most cases is not serious. However, it often becomes chronic, and is then "mixed," both anatomically and clinically. Such cases are usually the result of some concurrent cause, such as alcoholism, syphilis, la grippe, or the puerperal state, and the prognosis is then much graver than it is in the simple malarial form of nephritis. An important sign of the gravity of the affection is the presence, in the urine, of certain albuminoid substances of the group of albumoses, giving a violet-purple coloration, with a few drops of liquor cupropotassæ, after coagulation by heat.

Many other papers dealing with malaria were read, and there was considerable discussion. In the course of the discussion Professor Mariani (Genoa) stated that malaria is transmitted by anopheles, but not in all cases.

Dr. Walter Innes (Cairo) described the distribution of the anopheles mosquito in Egypt.

Professor Chantemesse (Paris) presented a long report on the serum-therapy of typhoid fever. He described the results of the application of his antityphoid serum to a large number of patients in French hospitals, and claimed for it that it helped man to resist the fever, and exercises in him the same preventive and curative effects, which experiments has shown it to possess in animals submitted to the typhoid virus. The result is a greatly lessened mortality, and a curative influence on local affections. The serum is anti-infectious and antitoxic, but, above all, it excites the activity of the phagocytes, and also of the leucopoïetic organs, which produce the phagocytes. The serum is especially valuable early in the disease.

Drs. J. Courmont and Ch. Lesieur (Lyons) stated that the bacillus of Eberth can be demonstrated in the blood of typhoid-fever patients in the early stages (*i. e.* up till the twentieth day) of the disease. As the bacillus can be demonstrated in the early stage of every true case of typhoid fever, before the Widal test is applicable, this fact is of the utmost importance for purposes of diagnosis. To isolate the bacilli, he inoculates 300 c.c. of bouillon with 2 to 4 c.c. of the patient's blood. As the result of a discussion, in which Professor Mariani described, at length, his researches in Professor Maragliano's clinic at Genoa, Dr. Courmont admitted that much still remained to be done in this field of research before its full scope could be thoroughly appreciated.

Dr. Ibrahim Pasha, the president of the Congress, read an interesting paper on tuberculosis in Egypt. He said that the Egyptian climate is not favorable to phthisical patients, accustomed to a warmer climate, but exercises a beneficial influence on European patients coming from places not of high altitude. The most favorable season is from October to April. At other times of the year the heat and the khamseen winds exert a deleterious effect.

Professor Maraglano (Genoa) read a very long communication on the treatment of tuberculosis, and laid some stress on the beneficial effects accruing from injecting into the human blood steam "defensive materials" prepared from the blood of healthy animals, such as the horse.

Dr. J. P. Langlois called attention to the efficacy of the impure sulphurous acid produced under pressure, and at a high temperature in the Clayton apparatus for disinfecting ships. It kills all kinds of infectious germs, rats, and insects, and does not appreciably affect the most delicate merchandise, nor exercise any deleterious influence on human beings.

Dr. Schuman-Leclercy (Carlsbad) described the beneficial effects obtained in a series of cases of severe diabetes by substituting, as far as possible, vegetable albumin for animal albumin in the food. He made an elaborate series of tests, both in cases fed on vegetable albumin, and a control series fed on the usual diet, and found a great gain in weight in the former group.

In the Section of Ophthalmology the whole time was taken up in discussing Egyptian ophthalmia and trachoma, which work such fearful havoc in this country. Dr. E. C. Fisher brought forward certain prophylactic measures, by means of which it is hoped that the frequency of these complaints may be lessened. These consist chiefly in the enforcement of the obvious hygienic measures: Supplying the villages with pure water, by means of wells, rather than permit them to use the polluted river water; removing cattle and horses away from the houses, so as to lessen the plague of flies, and endeavoring to instil into the people's minds the dangers of neglect of the elementary rules of hygiene.

Dr. Guzet (Lyons) described the application of photography to the study of certain ocular affections, and exhibited an admirable series of photographs of intraocular structures.

A large number of very interesting communications, of a nature which does not readily lend itself to condensation into the form of abstracts, were read in the various sections. In this class I might refer to several memoirs on native practice of medicine, the therapeutics of the ancient Egyptians, and similar topics; Dr. Engel (Cairo) gave an historical account of leprosy, especially in this country; Dr. Bitter (Cairo) described, in great detail, and with elaborate statistics, the course and means adopted for coping with the epidemics of cholera and plague in Egypt; Dr. Sandwith (Cairo) also described the clinical features of Egyptian pellagra, and Mr. Reginald Harrison (London) gave an account of the geographical distribution of urinary calculi—to mention only a few of the many interesting papers.

At the closing séance Professor Nothnagel (Vienna) gave a very interesting address, in which he urged the constant

and strenuous striving after the prevention of disease, and the highest aim and the ultimately attainable goal of medical practice. The address contained nothing strikingly new, and yet the happy expression of views, which every thinking practitioner must have, consciously or unconsciously, formulated for himself, formed a not inappropriate "corrective" at the end of a successful congress, when, for the moment, novel ideas and strange suggestions may have tended to dim the clear, guiding light of modern medical striving.

Progress of Medical Science.

The Boston Medical and Surgical Journal, January 15, 1903.

Vesical Appearances in Renal Suppuration. — Edgar Garceau describes a case the great interest of which lies in the two following points: First, that a suppurating kidney may exist in the body and that the corresponding ureteral eminence in the bladder may not be at all diseased. Second, that long-continued boracic acid vesical injections will and do, in these cases, reduce the intensity of the cystitis to almost nil. The diagnosis of a suppurating kidney in similar cases must be made by seeing purulent urine exuding from the corresponding ureteral orifice. In most cases of suppurative inflammation of the upper urinary passages, lesions will be seen at the site of the corresponding ureteral eminence, but as this sign is sometimes totally wanting, it is evidently not positive.

A Case of Retinal Hemorrhage in a Patient of Seventy-three; Treatment by the Faradic Current; Complete Recovery.—Hasket Derby began the treatment with the Faradic current in this case on October 17 and used it ten minutes at a time, three times a week, up to May 26. Small doses of iodide of potash were also administered during all this time. The peripheral hemorrhages began to be absorbed much more quickly than the macular. The patient's original vision was reached May 26 and treatment was suspended. In the following September not a single spot of hemorrhage was to be found in the fundus, a very slight grayish discoloration alone marking the site of the more extensive blood patches. The author says that the recovery may have been due to other causes than the use of the current, but it is surely an unusual instance of a *restitutio ad integrum* in a person of over seventy, of very full habit, and in an aggravated case. He hopes that other practitioners will apply the treatment and report the result. He also calls attention to the analgesic properties of the Faradic current, especially in iritis and iridochoroiditis.

The Treatment of Hay Fever.—Lorenzo B. Lockard considers the treatment of this affection under two heads—prevention and palliation. Preventive treatment must be both local and constitutional; the former may be summarized by saying, "Correct all abnormalities; if none exist, cauterize lightly the mucosa of those areas which are known to be particularly susceptible." The general treatment should be begun at least four weeks before an expected attack, and is given with three objects in view: an increase in elimination and decrease in production of uric acid; the correction of any existing neurosis; the removal of constitutional or local abnormalities. As for palliation after the attack is fully established, the author operates or cauterizes when such procedures are indicated by the local conditions. In all cases he administers nitro-muriatic acid (not the dilute) three to five drops after meals and before retiring. In only a few cases has it completely failed. Upon omitting a single dose, however, the symptoms recurred. For the nasal discomfort, adrenalin chloride is a remedy of great power. It is more efficaceous than cocaine, does not lose its power, no matter how frequently used, and has no deleterious local or constitutional effects. The adrenalin should be followed by an oily spray.

Journal of the American Medical Association, Jan. 17, 1903.

Syphilis of the Larynx.—C. M. Robertson describes the usual lesions and clinical appearances of specific lesions in the larynx, but nothing new is offered. A diagnostic table of the signs of syphilis, carcinoma, and tubercle is added. For internal treatment he combines mercury with iron and phosphoric acid. When the iodides are indicated he advocates the combination of iodide of potash with bromide of sodium, thereby is the tendency to iodism greatly lessened. Topically he prefers, as a cauterizing agent for specific ulcers, iodine crystals in creosote (to saturation).

Epilepsy; Its Psycopathology and Medicolegal Relations. —H. A. Tomlinson says that we have practically no anatomic basis for the psycopathology of epilepsy. It is probable, however, that those individuals who become epileptic do so because of some primary defect in the development of the brain which renders the cortical cells in the motor area abnormally unstable, so that causes of disturbance occurring in infancy, during the period of second dentition, or at puberty, may be sufficient to give rise to these explosive discharges of excessive motor activity, which we know as convulsions, and which have a tendency to become habitual. The fact that, in children, disturbances in the alimentary canal are the most common sources for the origin of the conditions which give rise to the convulsive outbreak, suggests that, as a result of the autointoxication, there are developed changes in the nutrition of the cortical cells, resulting in increased irritability and the production of these undue and untoward manifestations of motor activity. As to the medico-legal relations of epilepsy, we must determine, in case of a given act, bringing the epileptic within cognizance of the law, first, the nature act; next, how far it was habitual under similar circumstances; then the extent to which the epileptic was capable to, and did appreciate the significance of the act or acts, with relation to his environment. Finally, how and to what extent he might be able to appreciate his relationship to his fellows and control his conduct so as not to jeopardize their welfare; and in order to determine these facts we must understand his position in the family, community, society, and those abnormal conditions resulting from his disease, which might interfere with his relations to those about him.

The Mortality Following Operations for Pus in the Pelvis.—H. Robb offers the following conclusions: (1) The mortality following operations for suppurative diseases of the tubes and ovaries can be kept under 5 per cent. (2) The death rate is largely influenced by *a*, the virulence of the specific organisms present; *b*, the individual resistance of the patient; *c*, the time and manner of carrying out the operative technic. (3) The microorganism most to be feared is streptococcus pyogenes, but it must be born in mind that this organism varies considerably in virulence. (4) Abdominal drainage following operations for pus in the tubes and ovaries is seldom called for, as the organisms are generally dead. Drainage becomes necessary only when it has been found impossible to remove the suppurative structures, or where perforation of the bowel from the separation of dense adhesions is to be feared. Under these circumstances the best route is by the vagina. (5) The employment of sterile salt solution for irrigating the pelvic cavity will satisfactorily remove the pus or its products, and the filling of the abdomen with salt solution will dilute and promote the rapid absorption of any inflammatory products that may be left behind. (6) The elevated position for twenty-four hours following the operation, with the abdomen filled with salt solution, tends to prevent the intestines and omentum from coming in contact with the immediate field of operation, and as a result adhesions are not so likely to form between the viscera and the incised surfaces. (7) Should symptoms of infection follow the closing of the wound in pus cases, we have, as a rule, sufficient time to reopen the abdomen and wash out the infective material that may have been left behind, or that may have been introduced at the time of the operation. (8) Operations for pus in the tubes and ovaries from the standpoint of the pus *per se* are not surrounded by more danger, as a rule, than those in which a purulent focus is not present.

Medical News, January 17, 1903.

The Treatment of Acute Suppuration of the Middle Ear.—Wendell C. Phillips draws the following conclusions: (1) In acute middle-ear suppuration early and free drainage is of the utmost importance. (2) Patients should remain in bed until acute symptoms have passed. (3) Free purgation (preferably by means of calomel) should be resorted to. (4) Microscopical examinations of pus should be made. (5) Local treatment should consist of cleanliness and free drainage. (6) Proper internal medication should not be ignored. (7) Prolonged attempts to abort suppuration of the mastoid cells are to be condemned. (8) Early operative interference in mastoid suppuration prevents the more serious complications and gives far better hearing results. (9) Uncomplicated cases of acute suppuration of the middle ear, when properly treated, always recover in from two days to three weeks. (10) The reponsibility for preventive treatment must be largely assumed by the family practitioner. He should appreciate the importance of this when caring for grippe, the exanthemata, or other infectious intranasal conditions, and also the early and complete removal of diseased adenoid tissue.

Complications of Chronic Suppuration of the Middle Ear.—Robert Lewis, Jr., deals with those phases of the subject which are concerned with the etiology of the complications of chronic purulent otitis media, and of the frequency and serious nature of these complications.

First, there are those which relate to the parts primarily involved. The membrane tympani may be wholly or partly destroyed; the mucous membrane lining is partly or wholly replaced by granulation tissue and polypi; similar changes often occur in the adjacent related cavities; one or more of the ossicles are carious or destroyed; or there may be necrosis of the tympanic walls. Again, there are complications involving other auditory structures, as a necrosis of the petrous part of temporal bone with destruction of the auditory nerve; a cholesteatomatous mass in the mastoid antrum; or a mastoiditis of those parts of the mastoid process which have escaped eburnification. The result is an impairment or loss of hearing. The third group of complications involve other organs than those of audition. For example, one of the sinuses at the base of the brain may become involved in a septic inflammation, with the formation of a septic thrombus; the internal jugular vein or the carotid artery, even, may also be involved in a similar inflammation. There may be a pachymeningitis. or a laptomeningitis. or, from extension of the septic infection, an abscess cavity in the substance of the brain. Facial paralysis may follow an erosion of the Fallopian canal. There may be septic pneumonia or pleurisy or a metastatic abscess of liver or spleen or some other part of the body. A septic synovitis or gastroenteritis, or even a general pyæmic condition, may develop. There are many paths along which infection may travel from its original focus. Every case of chronic purulent otitis media must be treated as a disease that must be eradicated, no matter how simple the case may appear.

New York Medical Journal, January 17, 1903.

Topical Bloodletting as a Derivative and Revulsive Remedy in Congested and Inflamed Hemorrhoidal Blood Vessels and in Other Affections.—W. Bodenhamer refers to the older practices of venesection and arteriotomy, and deplores the fact that they have become so obsolete, for he does not believe that there are any other measures so valuable as these in pleurisy, pluropneumonia and sunstroke. Leeches applied to the ano-rectal region are beneficial not only in maladies of these parts, but also in chronic affections of the liver, spleen, colon, and contiguous organs. In hemorrhoidal prolapse the leeches should be applied not directly to the parts but at some distance. Similarly in certain affections of the feet it is better to abstract blood from the arm, In hemorrhoidal cases the best region for application, in the author's opinion, is the lumbar. From five to fifteen leeches may be applied daily, according to the condition of the patient, until he is relieved. After the acute inflammation has been subdued, operative measures may be considered in those instances in which the tumors have become regularly organized.

Intestinal Indigestion and Its Relation to Arterial Sclerosis and Renal Disease.—L. Weber gives the clinical histories of three cases exhibiting the sequence of events named in the title. Commenting on the fact that children with cholera infantum and similar acute and subacute gastrointestinal affections frequently suffer and die from acute nephritis, he says that he sees no reason why similar poisons continuously supplied should not produce chronic renal changes, especially those characterized by interstitial inflammation. The mode of action of these poisons is probably that brought forward by Ribert, who has maintained that the noxious agents coursing with the blood current do not attack the parenchyma directly through the capillarics. but get into the lymph spaces, and, in flowing from the periphery toward the hilum of the organs develop their irritating and deleterious influence upon both parenchyma and interstitial tissue. By the peculiar tractlike way in which the lymph channels and lymph nodules are arrayed beneath the capsula propria and within the cortical substance of the kidney, the focal distribution of the inflammatory process would then be explained. With reference to the treatment of these cases, the author says that it is self-evident that the administration of small doses of the iodides t. i. d. constitutes part of the treatment of established sclerotic disease; when disease of the kidneys is threatened through gastrointestinal indigestion, careful diet, intestinal antisepsis, *i. e.* calomel in very small doses, frequent cleansing of the colon, regulation of the patient's life, etc., will be of direct benefit and of the first order in our therapeutic measures.

The Mechanics of Flat-foot; Causative, Preventive, and Curative.—E. M. Thompson defines flat-foot and assigns as causes, rheumatism, rachitis, paralysis, general muscular weakness and trauma, either direct or indirect. The astragalus or keystone of the arch is the keynote of the condition. When we find a case of flat-foot, it is because this bone is dislocated downward, forward, and inward, owing to the stretching, tearing, or suturing of the inferior calcaneoscaphoid ligament. The scaphoid being now free, is "popped" outward by the pressure of the astragalus and superincumbent weight of the individual, the foot is abducted and everted; the middle cuneiform slips downward and the internal cuneiform slips outward, thus bringing pressure upon the plantar vessels and nerves, and giving rise to acute pain, which is transmitted to the legs and thighs, and even to the back via the anterior tibial, musculocutaneous, and external plantar nerves, all of which supply the mediotarsal joint. Many œdemas of the lower extremity are doubtless due to this cause. The following rules are given for reducing the dislocation: Grasp the foot firmly and extend it sharply on the tarsus (this increases the space between the internal cuneiform and the astragalus). Then forcibly invert and abduct the foot and flex it again to 90°, maintaining the adducted and inverted position. This will bring the scaphoid back into place and reestablish the relations of the arch. With the foot held in this position adhesive plaster straps are applied firmly, by attaching one end over the instep and bringing the other end over the outer side of the foot, under the sole, and upon the inner side of the foot, crossing over in front of the ankle-joint and up around the calf in a spiral manner to just below the knee. A second, third, and fourth strap are applied in the same manner. Short straps may be applied anteroposteriorly around the heel, crossing at the instep to hold the foot more firmly, but these are not essential. Plaster of paris is applied in aggravated cases (in which an anæsthetic is used) in the same manner and after the same method of reduction. This dressing holds the foot in varus, or inversion. The adhesive plaster straps must, of course, be a temporary dressing or be renewed frequently. They are usually employed while steel insoles or braces are being made.

American Medicine, January 17, 1903.

The Etiology of Endocarditis, with Especial Reference to Bacterial Agencies.—Sanford Blum gives the following classification of endocarditis with reference to its etiology: (1) Congenital and infantile endocarditis may be due to defective development, to reparative processes as suggested by Parrot and to other causes (unknown). (2) Endocarditis due to known bacterial agencies, *e. g.* streptococcus staphylococcus, tubercle bacilli, pyocyaneous bacillus. (3) Endocarditis of probable bacterial origin, associated with definite diseases, presumably of a bacterial nature, but of which the bacterial agents are still undiscovered, *e. g.* rheumatism, chorea, syphilis, exanthems, etc. (4) Endocarditis due to mechanical or chemical results, *e. g.*, blows, strains, noxious excretory products in the blood, alcohol, atheroma.

A Contribution to Pernicious Anæmia.—O. E. Lademann states that the pathologic changes found in pernicious anæmia are by no means agreed upon, though the consensus of opinion is toward an "achylia gastrica" (Einhorn) as the existing lesion. It is still more unsettled as to whether the hæmolysis is due to the absorption of some toxic material in the alimentary tract, or whether it is a primary hæmatogenesis. The writer believes the former the more plausible, and upon this assumption he bases his therapy, which consists of daily irrigations of the intestinal tract. He does not believe that arsenic approaches a specific in pernicious anæmia. He reports a case in which the therapy consisted of daily lavage of the stomach with 1,000 to 2,000 c.c. of water and high enemas of 1,000 c.c. The diet consisted chiefly of milk, eggs, and milk preparations. Fowler's solution was given for twenty days.

Diphtheria Antitoxin in the Infectious or Bacterial Bronchopneumonia of Childhood.—Joseph O'Malley reports three of these cases. In all, defervescence occurred by lysis within eight to ten hours after the serum was used. The cases were unusually severe. The first time that the writer used the serum he did so because of the proximity of a case of diphtheria, thinking the bronchopneumonia was of bacillary origin, perhaps due to Klebs-Löffler bacilli. The remarkable results caused him to use the same treatment in bronchopneumonias complicating the exanthems. Since then he has used the serum in like conditions with uniformly satisfactory results. He has also used it in scarlet fever in which the anginal symptoms were pronounced, and he obtained a rapid amelioration of this and all of the other distressing symptoms. He believes that the serum is a most valuable therapeutic agent in a class of cases otherwise beyond ordinary therapeutic aid, particularly in bronchopneumonia complicating the bacterial diseases of childhood.

Philadelphia Medical Journal, January 17, 1903.

Two Erroneous Surgical Decisions in Intestinal Perforation from Typhoid Fever.—John B. Roberts discusses these cases, reported above, in a most instructive paper, and concludes, from their careful study, that: The occurrence of pain and the increased rate of pulse and respira-

tion are probably the most valuable early diagnostic symptoms of perforation. The count of leucocytes seem to have little value, unless it be hereafter proved that a count of the polymorphonuclear leucocytes has diagnostic significance. A sudden fall in temperature is not a necessary accompaniment of perforation.

Two Cases of Perforation in Typhoid Fever, in One of Which an Operation Was Performed.—James Hendrie Lloyd and Thomas Luther Coley present this paper. In the first patient, a man fifty-two years old, the fever from its outset was not regarded as severe. There was no difficulty in controlling the temperature. There was no diarrhœa, nor more than a slight degree of tympanites. He disliked milk, but no symptoms followed its administration till noon on the thirteenth day of the disease, when a sudden attack of pain with vomiting occurred. With the onset of the pain there was neither a drop in the temperature nor appreciable change for forty-eight hours in the pulse or respiration. With the increase of tympanites, the liver dulness could be well made out, and there was no exquisite or even general pain on abdominal pressure. The leucocyte counts, which were made during the afternoon of the day in which the pain occurred, varied between 7,200 and 8,000. It is questionable whether these figures should be regarded as a leucocytosis, even admitting the leukopenia, which is present in typhoid. From the time of this attack of pain the patient grew worse, and in five days he died. The perforation was found nine inches from the ileocæcal valve, and was one-eighth of an inch in diameter. In the second patient the fever and tympanites were both greater in degree than in the first case. At the time of the first attack of vomiting the temperature was 100°, respirations 44, pulse 120. Four hours later there was a second attack of vomiting, at which time the temperature was 102°, pulse 116, respiration 36. The general character of the temperature-curve was very similar to that of twenty-four hours before, with the difference that at that time the respirations were 20 and the pulse 88 and 90 respectively. The difference in the respiration rate, at which time the perforation probably took place, is suggestive. The symptoms in these cases gave small indications of the presence of extensive perforations and fecal accumulations in the abdominal cavity. More extended observations in similar cases are greatly needed, for the early recognition of perforation is imperative if the patient is to be saved by surgical intervention.

The Lancet, January 10, 1903.

The Diffusibility of Scarlet-fever Virus.—J. Rutherland believes that the scarlet-fever virus has a low diffusibility—that is, the poison is not carried from the sick by healthy persons who themselves escape but infect others. He has never found a satisfactory explanation of this mediate contagion. From observation of various outbreaks, he was cognizant of no less than eighty-two different sets of circumstances, each of which was, so far as our present knowledge goes, in every way calculated to promote the transmission of infection in the manner specified, yet no such transmission occurred. This absence may be due, he thinks, to the weight of the desquamating scale containing the virus, the drying and rapid devitalization of the latter, or some cause or condition as yet unsuspected. This matter is quite distinct from the intensely contagious nature of the disease, for the author has seen only one single instance of a susceptible child escaping after contact with a desquamating case.

Intravascular Antisepsis.—Injections of various compounds have been made by J. M. Fortescue-Brickdale. From his first series of experiments he concludes: (1) Perchloride of mercury, oxcycyanide of mercury, and protargol cannot be injected intravenously into rabbits in sufficient strength to produce an antiseptic effect lasting over several days. (2) A mixture of chinosol and formic aldehyde is too toxic, even in minute doses, to be of use for practical purposes. (3) Chinosol or formic aldehyde can be injected intravenously so as to produce a solution which would have an inhibitory action *in vitro*. (4) Sodium taurocholate can be injected in small doses, but that toxic effects manifest themselves after a few days. In a second series of experiments, the effects of injections of the foregoing substances on infected animals were investigated. Conclusions are as follows: (1) Rabbits injected daily with non-toxic doses of oxycyanide of mercury, formic aldehyde, chinosol, protargol, or taurocholate of sodium are not thereby protected from the usual effects of a previous inoculation of virulent anthrax; and (2) chinosol and formic aldehyde in large doses (toxic) so depress rabbits infected with the pneumococcus that they die sooner than an untreated animal.

An Improved Method for the Microscopical Diagnosis of Intermittent Fever.—R. Ross calls attention to the difficulty in detecting the malarial organisms from the obscuring effect of the massed corpuscles. He, therefore, washes out the hæmoglobin from the capsules. His method is described as follows: A large drop of blood, amounting to, say, 20 mm., is taken up on the glass slide or cover-glass and is slightly spread out by means of a needle or lancet—that is, it is spread over an area which can be covered by an ordinary cover-glass. It is then allowed to dry, either naturally or over a flame (without heating so much as to fix the hæmoglobin). The result is that we have a thick dried film of blood in which about 2 c.mm. of blood (instead of the 1 c.mm. generally used) are disposed over an area which is not larger than the area of blood usually examined by the ordinary processes. As soon as the film is perfectly dry, he lays upon it, by means of a glass rod, a quantity of aqueous eosin solution sufficient to cover the film of blood. The solution is the one which is usually employed in order to obtain the Romanowsky effect. It is allowed to remain upon the film of blood for a period up to about a quarter of an hour. This period should be inversely proportionate to the strength of the solution. As the film of blood has not been fixed, the solution of eosin will take out the hæmoglobin of the dried corpuscles, and, at the same time, will stain the residual mass consisting of the stromata of the corpuscles, the leucocytes, blood-plates, and parasites. After the solution has remained upon the film for the period required it is washed off by a very gentle stream of water. As the film has not yet been fixed to the glass, it is most essential here to use no strong current of water, or else the whole of the residual mass will become detached from the surface of the glass. As soon as the eosin solution has been washed out a weak solution of the methylene blue, which is employed for the Romanowsky stain, is allowed to run over the film, just as was done for the eosin solution. The blue is permitted to remain only for a few seconds, the time varying inversely with the strength of the solution. Especial care must be taken not to stain the preparation too dark a color. Next the blue is washed off very gently in its turn and the preparation is complete. We can now dry the stained film and mount in Canada balsam, or examine it directly by placing a drop of cedar oil upon it for the immersion lens; or we can mount it in water, place a cover-glass over it, and examine as usual.

British Medical Journal, January 3, 1903.

Purpura Hæmorrhagica Following Sea Bathing.—Edward Tonge reports the case of a boy of five years who had had perfect health up to the time when he took his first sea bath. The day after, his temperature was 101.2° F., and he was suffering from vomiting, sever pain in the lumbar region, and a slight petechial rash on the chest. The next day he became anæmic, there was a hæmatoma in the left popliteal space the size of an egg and various ecchymoses. The temperature was normal. The urine and stools contained blood. A slight systolic murmur was heard in the left axilla. A week later the whole left side of the body was convulsed. Convalescence was delayed for two months, but he recovered.

The Diagnosis and Treatment of Various Forms of Septic Synovitis.—F. C. Wallis, in speaking of the differential diagnosis between septic synovitis and rheumatic fever, calls attention to the fact that profuse sweating is invariably present in an attack of rheumatic fever. Two symptoms which are nearly always present in septic conditions, and upon which he depends to a considerable extent in making his diagnosis, are the dry, harsh, unpleasant condition of the skin, and more particularly the restless, distressed, unhappy mental condition which exists in these patients. Monarticular synovitis, coming on suddenly in young people without any known reason, is always suggestive of gonorrhœa. If after a week of expectant treatment the joint still remains distended and shows no sign of amelioration, the joint should be opened and washed out with warm saline solution. The incision is then carefully closed. At the end of from ten to fourteen days of rest, when the incision is quite healed, the joint may gradually be used again, when massage will be beneficial. Synovitis may follow influenza. When associated with osteomyelitis the joint should be opened at once on account of the greater virulence of the microorganism, and the consequent rapid destructive changes. It may even be desirable to drain the joint for a day or two. In synovitis due to streptococcus infection, the joint must be opened freely, drained and irrigated often. The question of a movable joint is of secondary importance. The chief object is to keep the limb and preserve the patient's life. In pyæmic synovitis the rapid production of pus is really a safeguard, for the physician is then apt to open the joint promptly, drain and irrigate it—treatment which tends to preserve the limb. No joint can be properly washed out through a trocar, and no harm can follow early excision and irrigation when properly done.

Fourteenth International Medical Congress.

To Be Held in Madrid, April 23-30, 1903.

FORMER INTERNATIONAL MEDICAL CONGRESSES.

In the preparation of the following historical sketch free use has been made of the data upon the first nine congresses furnished by Sanitätsrath Dr. S. Guttmann, in the *Deutsche medicinische Wochenschrift* for 1890. As Dr. Guttmann remarks, on a general survey one observes that every one of these congresses has been organized under the most different conditions, and every one has presented an attempt at reform. Some of these reforms have been enduring, while others have lapsed, and have been replaced by new ones.

The *First Congress* was held at Paris in 1867. The first proposition of an international medical congress originated at the annual meeting of French physicians at Bordeaux in 1865. It was based upon the expectation that a great many physicians from all countries would find themselves together at the World's Exposition in Paris in 1867. The committee in charge of arrangements, under the chairmanship of Bouillaud, submitted a program of seven questions relating to anatomy, physiology, surgery, internal medicine, and public hygiene. The international character of the meeting was marked by the participation of delegates from various countries, and from many foreign learned societies, and by the nomination of six foreign vice-presidents, of whom Virchow was one. The Congress was held without any such ceremonies as official hospitalities and general festivities, which have come to occupy so prominent a place at these meetings. The Congress comprised 333 French and 589 foreign members. In his opening address, Bouillaud said: "We celebrate to-day a great fête, than which the history of medicine can cite no greater." Among the questions propounded were: Tuberculosis in different countries, and its influence on mortality; the possibility of proposing efficacious measures for the restriction of venereal diseases; the influence of alimentation, climate, race, and conditions of life in different countries, upon disease. The cost of publication of the proceedings of the Congress was defrayed by contributions.

During the second evening session, Dr. Pantaleoni, one of the delegates from Italy, expressed the wish that this international meeting of physicians might be the first of a long series, thus originating the idea of periodical international medical congresses. At a subsequent session, at which several nations were named as desirous of entertaining the next Congress, considerable doubt was expressed as to whether a congress could be got together without the extraordinary incentive of a universal exposition in one of the greatest cities of the world. Nevertheless, votes were taken, and Italy was unanimously selected as the country in which the second "Olympiad," as Bouillaud termed it, should be held. After consultation among themselves, the Italian delegates named Florence, the then capital of Italy, as the place of meeting.

The *Second Congress*, accordingly, was held at Florence from September 23 to October 2, 1869. Seven questions were propounded, among which were: Marsh miasm, the conditions favoring its developments, its effects, and the most efficient methods for combating it; the therapeutics of cancer; the treatment of gunshot wounds; the hygienic conditions of hospitals; the conditions favoring epidemics in large cities, and the means for prevention; the rights and duties of physicians in regard to legislation in different countries, and the ameliorations which can reasonably be expected therefrom. Evening festivities, an excursion to the hot springs of Monte Catari, and a resplendent banquet, tended to multiply and to knit more closely the international relations among the participants.

The *Third Congress* was delayed two years by political events, and by the desire to assimilate it to the time of the Vienna Exposition of 1873. The committee, consisting of Vienna physicians, under the chairmanship of Rokitanski, suppressed the chief provision of the program of the Congress of Paris, which limited the discussions of the Congress to purely scientific matters, and embarked upon a consideration of an admixture of legislative and hygienic problems. The Austrian Ministers of Commerce and of Foreign Affairs wished to avail themselves of the occasion to reach a conclusion upon the subject of quarantine, and all the questions provided in the program related to hygiene. The discussion is noteworthy as the first upon cholera. The establishment of quarantine by land and river, and the maintenance of sea quarantine were favored, and the Congress desired the formation of an international commission for the investigation of the cholera virus. Compulsory vaccination was also recommended to the European governments. While in Paris an international stamp had been impressed upon the Congress by the choice, from all countries, of a number of leaders for the discussions, the Organization Committee chose only Vienna physicians as leaders. The Congress preserved, however, its international character through the great number of delegates from the governments of the various countries, and by the naming of foreign presidents and vice-presidents, who were entrusted with the conduct of the discussions. In spite of the deviation which gave the Congress of Vienna rather the form of a hygienic congress, this Congress, on its part, incontestably contributed to progress by the limitation of work to one instead of two weeks, without a diminution in the number of the sessions held at Paris and at Florence. A second step taken was the permission granted for the use of additional languages.

The *Fourth Congress* was held from September 19 to 25, 1875, at Brussels, under the presidency of Dr. J. F. Vlemingkx. To Warlomont and Crocq the organization of the Congress was indebted for an essential reform in the arrangement of the sections along the lines of the various branches of medical sciences. The realm of medicine was thus resolved into a number of specialties which secured greater depth in the treatment of the questions raised. This process of division is a universal one. Its conditions lie not alone in the increase in the matter of the sciences, but as much in the refinement and complication of methods. In every way interest was heightened by this arrangement. The number of the questions prepared, and of the reports which were under discussion, was considerably increased. A further progress which marked this Congress was the exhibition of newly introduced and progress-marking instruments for study and practice, and an inspection of the sanitary arrangements of the city of Brussels. At this Congress also there were a number of delegates from the governments of the various countries. But instead of the foreign presidents and vice-presidents, there were numerous honorary presidents, both for the general meetings and for the sections, who, however, seldom

acted in place of the President of the Committee of Organization. The latter reëstablished that article of the statutes which preserved to the Congress its essentially scientific character. The principal topics of discussion were the prevention of cholera, the rôle of alcohol as a therapeutic agent, surgical anæsthesia, the organization of the public hygiene service, and the disposition of the criminal and dangerous insane.

The *Fifth Congress* took place at Geneva from September 9 to 15, 1877. The membership was less than 500. Prof. Carl Vogt was elected president. This Congress reëstablished the practice of the Congress of Paris of seeking leaders of the discussions in all countries. Professor Bouchard read an extensive paper on the etiology of typhoid fever, calling attention to its dissemination by the air and water, and he discussed the effect of sewer gas on the health of workers in the sewers. Professor Vogt spoke on the entozoa of man. Doctor Broadbent discussed cerebral localization. Professor Schiff maintained that the function of the spleen is not blood forming, but that it is accessory to digestion, furnishing necessary products to the pancreas. Professor Lombard spoke on malaria in Europe. Professor Revilliod discussed diphtheria and croup, maintaining their identity. Esmarch discussed the advantages and disadvantages of his well-known bloodless method of operating. Marey reported on the electric discharge of the torpedo eel, which he considered analogous to a muscular discharge. Professor Magnan gave his conclusions on the relation of alcohol to insanity. The practice adopted at Vienna of settling administrative and legislative questions by majority vote was discontinued, beginning with this Congress.

The *Sixth Congress* took place at Amsterdam from September 7 to 13, 1879. The membership was under 500. This Congress was marked by Lister's discourse on his antiseptic method of handling wounds, and also by Virchow's address upon the preliminary education of physicians. Professor Donders, the President of the Congress, spoke on the condition of medical science, and emphasized the importance of experimental physiology to its future growth. Dr. Sayre gave a demonstration of the value of his plaster-of-paris jacket in spinal diseases. Dr. d'Arsonval described an apparatus for the exact measurement of the amount of heat given off from the body. Hydrotherapy in fevers was discussed, and two fairly good papers on metallotherapy were read by Eulenburg, and by Drs. Proust and Ballou. Bright's disease was discussed at length, and Semmola advocated the view that the disease is general, and only secondarily local; that the action of moist cold on the skin is the only cause, this checking the respiratory function of the skin, whence result abnormal changes in metabolism and in the blood, and finally changes in the kidney.

The *Seventh Congress*, held at London, from August 3 to 9, 1881, had a membership of 3,182, and was of all the congresses up to that time the most successful. The notables of science from all lands were present, the entertainments were well planned and brilliant, the section work was diligently conducted, and the amount and value of the work done was great. The Lord Mayor's dinner at the Mansion House, the soirée at the Guildhall, and the conversazione given by the English members at South Kensington, were the chief social functions. An invitation was extended to the Congress to visit the International Sanitary Exhibition at the Parkes Museum. By a large majority, the committee decided to limit the invitations to the Congress to men, which brought out a protest from forty-three duly qualified medical women. Pasteur reported upon his investigations of chicken cholera, and upon protective inoculation against splenic fever. The latter paper the *Lancet* considered "the most valuable of all those delivered," and it hazarded the prediction that perhaps the Seventh Congress might be famous in history on account of it. Virchow spoke on vivisection as an indispensable aid in research, and made a powerful plea for perfect freedom of investigation, showing conclusively that our present knowledge of life is the result of experimentation, and that the only reliable and practical method for the increase of that knowledge is also experimentation. Professor Huxley gave a masterly address upon the relation of the biological sciences to medicine, in which *inter alia*, he spoke of Harvey as the last of the ancients rather than as the first of the moderns, and dated the modern era of medicine from the time of Descartes. In the Pathological Section the discussion on the relation of microorganisms to disease was opened by Lister. Professor Volkmann of Berlin read a paper on the results attained during the first ten years under the antiseptic method. Dr. J. S. Billings spoke on "Our Medical Literature," and the posthumous paper of Raynaud on "Scepticism in Medicine" was read.

The *Eighth Congress* was held at Copenhagen, from August 10 to 16, 1884. On the whole it was a success. The attendance was large (over 1,700 members registered), and the resources of the Danish capital were somewhat taxed, but Danish cordiality caused this Congress to be remembered as one of the most hospitable. Professor Panum of Copenhagen was the President. Pasteur described the results of his protective inoculation of dogs against rabies. Sir William Gull of London advocated international collective investigation of disease. Antiseptic methods came in for a full discussion, which was opened, in the absence of Lister, by Esmarch. Virchow spoke on metaplasia. Dr. Sayre demonstrated his plaster-of-paris jacket, which, being new to many, attracted much attention. Tommaso-Crudeli exhibited specimens of malarial blood showing anilin-stained inclusions in the red blood cells, which he regarded as the germs of the disease. McEwen described his operation for genu valgum, and several surgeons announced the relinquishment of their operations in its favor. Cancer of the rectum was thoroughly discussed, the subject being opened by Esmarch. Tuberculosis was not forgotten. Goldscheider gave an interesting address on the specific sensibility of the skin.

At this time was inaugurated the publication in the Medical Record of a special cabled report of the proceedings of the Congress.

The *Ninth Congress* was held in September, 1887, at Washington. The omens were not propitious, and the future historian of American medicine will, we imagine, get out his mantle of charity when he approaches this part of his subject. Dr. Guttmann's estimate of the importance of this Congress may be inferred from his giving the place and date of meeting, with the observation that the action of the American Medical Association in abrogating the Committee of Organization appointed at Copenhagen, and the arrangements it had made, injured the Congress, as the event proved, by causing many of the most prominent medical men in America, and nearly all of those in Europe, to stay away. Unfortunately, Dr. Guttmann is not far wrong. The process of "high dilution" to which, on their return, the distinguished men who had secured the Congress for America, were subjected, resulted in their speedy

retirement from the management of the enterprise. There was then given ample opportunity of learning that to have a "congress" it does not suffice to go to it, but that a successful one is dependent for its éclat upon the presence of the great ones of earth who, however much they may in deference to the regnant fashion of ostentatious humility, bow their acknowledgments of "the honor conferred on them," etc., know well enough that the obligation really lies on the other side. Certainly, the most patent thing about the Washington Congress was the extremely small number of distinguished foreigners present, and its consequently tremendously one-sided character, from an international point of view. The entertainments were, perhaps, as good as could reasonably be expected, considering that the Government did nothing, and that the meeting took place at a season when Washington is bare of people of prominence. A reception was given by President and Mrs. Cleveland at the White House, and at the Pension Hall there were given a banquet, by the American medical editors, and a buffet lunch for 5,000. A reception was also tendered to the Congress by the citizens of Washington. The Congress was opened by President Cleveland, and Dr. N. S. Davis was elected president. Compared with other Congresses the principal distinctive features of the medical work were the large number of papers, their almost exclusively "practical" character, and the large number taking part in the discussions. Indeed, the great number of the papers precludes the possibility of their analysis, and we can only name a few as *primi inter pares*. Dr. Körösi gave an exceedingly valuable critique of our actual knowledge of vaccination, and showed that compulsory vaccination in the United States might be expected to save 120,000 lives, with a debit of 300 infant deaths as the result of the operation. Dr. W. H. Welch spoke on the effects of vaccination during the incubation period of smallpox. The Section on Psychological Medicine listened to papers by D. Hack Tukee and J. B. Andrews on the care of the insane in the United States and Great Britain, and discussed the association of syphilis and general paresis and the subject of moral insanity. Dr. A. R. Robinson read a paper on alopecia areata, and demonstrated the presence of deep-seated microorganisms. Dr. G. A. Atkinson presented a report on the chemistry and pharmacology of the nitrites and nitroglycerin. Dr. August Martin spoke at considerable length on vaginal total extirpation of the uterus for cancer. On the whole, the scientific work of the Congress, while respectable, fell much below the average of the two preceding congresses.

The *Tenth Congress*, held at Berlin, from August 4 to 9, 1890, was successful, as regards both numbers and scientific work. At one time it seemed as though French physicians might stay away on account of political animosities, but the French Government appointing its official delegates, nearly 200 French physicians ultimately participated in the Congress. Some 7,000 members were registered, 683 of whom were from America. Virchow was unanimously elected president. Among the papers, the principal feature of the Congress was the address of Koch, in which he reviewed the progress of bacteriology, maintained the causal rôle of microorganisms in disease, and expressed the belief that we were on the eve of practical therapeutic developments, as he had succeeded in immunizing guinea-pigs against tuberculosis, and also in arresting the growth and multiplication of the tubercle bacillus after inoculation. Lister reviewed the theories of immunity, dwelling on Metchnikoff's theory of phagocytosis, and expressed himself a firm believer in antisepsis as against asepsis. Professor Bouchard propounded a theory explanatory of immunity and infection; organisms resist disease by phagocytosis and by reaction into a bactericidal state; when bacterial toxins paralyze the vasodilator center, local exudation, diapedesis, and phagocytosis become impossible, and the disease develops, to be limited later by the development of the more slowly accruing bactericidal state. Professor von Bergmann lectured on his aseptic methods, and Billroth presented his statis tics, for the ten years under antiseptic methods, of resection of the stomach and intestines. Mr. Victor Horsley's paper on brain surgery, and his demonstration of the cortical centers for the larynx, were well received. An interesting discussion took place on refractive errors, and the opinion was expressed that if they were properly corrected, there would be no asthenopia. The section organization was characterized as wretched, no lists being furnished of the members, and the program of the papers being very incomplete. The complaint was made that papers in English received scant attention. The exhibition held in connection with the Congress was extensive and interesting, embracing all kinds of instruments of precision. The social side was well planned and well taken care of. The most notable social event was, perhaps, the reception in the Rathhaus, where the tables were loaded, and wine was "on tap" for 5,000. One of the most enjoyable excursions was that to the Havel Lakes, given by the Laryngological Society of Berlin to the Laryngological Section. At the parting feast beer flowed freely, and about midnight Virchow was induced to make a speech, and was finally seized and carried around in triumph.

The *Eleventh Congress* was held at Rome, from March 29 to April 5, 1894. Prof. Giulio Baccelli was president. Over 7,600 members were registered, more than half of them from Italy, which led to the inclusion of Italian among the permissible languages, and gave occasion to a renewed discussion in the journals on the remedy for the confusion of tongues. The MEDICAL RECORD had previously offered the suggestion of modern Greek as the international language of science, but we regret to say there seems to be no prospect of its adoption. America contributed fewer than 200 members, most of them from Mexico. Virchow lauded Mascagni's substitution of research for mere interpretation of authority and hypothesis, in anatomical work. Professor Babes sketched the work of the Roumanian Health Institute, emphasized the immense service already rendered by bacteriology, and made an earnest plea for an educational propaganda, especially among legislators, for the enactment into law of advances in our hygienic knowledge. Prof. Michael Foster urged organized effort in science, saying that many untrained youthful enthusiasts frittered away their unguided energies, and holding that the remedy lay in an international bureau for the correlation of effort. Dr. Laache spoke of idiopathic hypertrophy of the heart, and degeneration of the cardiac muscle; the chief causes of the former were alcohol and over-athleticism: yet, though the latter was very common in Norway, at a discussion before the Christiania Medical Society no case of permanent heart injury was reported from this cause; and athletics, with gradual training, and in reason, offered the best means of developing the muscles and strengthening the heart. Dr. Jacobi delivered an address with the title, "Non Nocere," in which he deprecated the tendency to subordinate the scientific work to the social features, and emphasized as the principal sins of omission at critical junctures, the neglect of intubation and

tracheotomy, of venesection in pneumonia, and of treatment of asphyxia neonatorum and of the so-called chronic constipation of infants; and among those of commission, over-dosing, over- and underfeeding of infants, the use of sterilized milk as their only food, and the resort to craniotomy for macrocephaly and idiocy. The Medico-Hygienic Exhibition resembled our drug exhibits, but contained some features of the non-commercial class, such as models of hospitals, cemeteries, and crematories, and a description of Paglioni's Bureau for improving the health of Rome. There were the usual social festivities, which included the lighting up of the various ruins at night, and the throwing open of the gardens of the Quirinal. Nevertheless this Congress was almost unanimously voted a failure by the medical press of the world. The inconveniences were partly due to a preparation for some 4,000 guests, instead of which nearly double the number came; and partly to lack of management, for which the officers, of course, came in for their full share of censure. The arrangements for the meetings were defective, one of the principal buildings being three-quarters of a mile from the cars, and the cabmen, after the manner of their race, embraced the opportunity for outrageous exactions.

The *Twelfth Congress*, held from August 19 to 26, 1897, at Moscow, was one of the pleasantest of these gatherings, yet for no other did the prospects seem more gloomy. The proposed exclusion from the sections of the English language in favor of Russian, the question of the welcome which physicians of Hebrew faith might expect in Russia (which led Virchow to announce a contingent "boycott" of the Congress), and the enforced resignation of the Secretary-General, Dr. Erismann, in consequence of his dismissal from the Chair of Hygiene at the University of Moscow on account of "liberal" tendencies, naturally created much irritation in western countries. The clouds, however, rolled away; English was restored, and an Imperial ukase granted members of Hebrew faith the same privileges as other members. The rubicon once crossed, nothing could have been more hospitable than the attitude of Russia—government, profession, and people. The members were made to feel that they were the nation's guests; they were everywhere transported on the railways free of expense, and in St. Petersburg, after adjournment and hundreds of miles from the place of meeting, they were still held to be guests for whom free entertainment was only the proper thing. Those who went on the excursion to the beautiful scenery of the Caucasus, and on that to the Crimea, were loud in their praises of Russian cordiality. Many members had thought of Moscow as a medieval, oriental city, but they found its medical institutions strictly up to date, and noted with surprise the confident spirit of pan-slavism which considers that the future belongs to it. To commemorate the meeting the city of Moscow founded a research prize of $1,000 for the congresses in perpetuity. The membership of the Congress was about 7,300, 120 delegates being from the United States. The scientific work presented nothing very sensational, most of the papers covering routine medical subjects, so to speak. Virchow reaffirmed his belief that the grand truth of unbroken cellular succession would never be overthrown, and, rather inconsistently, expressed the hope that the solution of the life problem might be announced at some future congress. That hardy perennial (as Huxley would have called it) tuberculosis came in for its full share of discussion, and the use of Koch's tuberculin was reported upon. The diagnostic and therapeutic value of serums was discussed; for typhoid fever by Widal and others, and for relapsing fever by Lowenthal and Metchnikoff. The latter also discussed the bubonic plague, and said that the general use of Yersin's serum would immunize the world. Professor v. Krafft-Ebing discussed the etiology general paresis, maintaining that the predisposing cause was the nervous over-tension of modern life, and the exciting cause, syphilis. Lombroso spoke on the application of psychiatric methods to the study of criminal man. In the surgical section the radical treatment of hernia, appendicitis, and brain surgery were discussed at length. Several cases of successful suturing of arteries were reported, among them one by Dr. J. B. Murphy of successful resection of 0.6 inch of the subclavian. Dr. Joannescu recommended splenectomy when long-continued medical treatment for malaria had failed; after the operation the malarial cachexia and the urotoxic coefficient decreased and the red blood cells increased. Dr. Semotzky reported a method of gastroenterostomy by which the passage of bile and pancreatic fluid into the stomach, entailing vomiting, was avoided. The Moscow prize was awarded to M. Henri Dunant for his organization of the International Red Cross Society.

The *Thirteenth Congress* held at Paris, from August 2 to 7, 1900, had a membership of over 6,000, with very few English, and some 350 Americans. The assassination of the King of Italy had cast a gloom over the French capital, and practically all the official fêtes were postponed. The opening of the Congress by the Minister of Justice (instead of President Loubet, as planned) was described as a monotonous and dreary function. Professor Lannelongue was elected President. His reception to some 1,200 members was the chief social feature. There were also a large reception given in the Senate Hall by the Bureau of Organization, a banquet by Prof. Charles Richet and the Scientific Society to Lister, and, on August 10, a reception by President Loubet. The private entertainments which had been planned were carried out. One of the features of the meeting was the large number and variety of the hospital attractions, and even after adjournment we find the medical Oliver Twists listening to a lecture by Hayem on his methods of studying the blood. The opening session in the Salles des Fêtes was attended by some 15,000 people. President Lannelongue's address emphasized the value of international medical congresses in promoting international intercourse, breaking down prejudice, and cementing the bonds of a common humanity. The scientific work offered nothing epoch-making. Virchow spoke on traumatism and infection. Professor Pavlov presented a paper on experimental therapy as a new and extremely fecund method of physiological research. Dr. A. Jacobi of New York spoke on medicine and physicians in the United States. Prof. B. Tarnowsky analyzed the statistics of twenty-five syphilitic families to the fourth generation. The prevention of syphilis in armies was discussed by Col. J. L. Notter. Professor Ehrlich spoke on his theory of the action of toxins. Professor Flechsig spoke on projection and association centers, and the paper was discussed by Monakow. An animated discussion took place on autointoxication, which was participated in by Bouchard, Ewald, Albu, Gautier, and Brouardel; the majority accepted, provisionally, Bouchard's theory. Radiography in fractures and dislocations was treated of by v. Bergmann and by Manoury of Chartres. Surgery of the pancreas came in for a full discussion by Professor Ceccherelli of Parma. The Moscow prize was awarded to Professor Ramón y Cajal for his great work on the nervous elements.

PROGRAM OF THE MADRID CONGRESS.

Officers of the Congress: *President*, Prof. Julián Calleja y Sánchez; *General Secretary*, Dr. Angel Fernández-Caro; *General Treasurer*, Prof. José Gómez Ocaña.

National Committees, UNITED STATES: *President*, A. Jacobi, New York; *Secretary*, John H. Huddleston, 126 West Eighty-fifth Street, New York. CUBA: *President*, Manuel Bango y Léon, Havana; *Secretary*, Agustín Varona y González del Valle, Havana. GREAT BRITAIN and IRELAND: *President*, F. W. Pavy, London; *Secretaries*, D'Arcy Power and P. Horton-Smith, London.

REGULATIONS.

Article 1.—The Fourteenth International Congress of Medicine will meet at Madrid, under the patronage of their Majesties, the King Don Alphonso XIII and the Queen Mother, April 23 to 30, 1903. The opening session will take place on April 23, and the closing session on April 30. The character of the Congress is purely scientific.

Article 2.—Members of the Congress will be physicians, pharmacists, veterinary surgeons, and other persons working at branches of medical science, both Spaniards and foreigners, who have entered their names and paid their subscriptions. Other persons who possess scientific or professional titles, and who wish to take part in the work of the Congress, may share in it under the above conditions; in this category are included representatives of the press.

Article 3.—The subscription is thirty pesetas. This sum must be paid before the opening of the Congress, to the General Secretary, Faculty of Medicine, Madrid. A card of membership will be sent to the subscriber. This card will confer all of the privileges reserved for members of the Congress.

Article 4.—The national committees of the different countries may receive the subscriptions of their own countrymen. After these have been sent to the General Secretary at Madrid, he will send to the subscribers their cards of membership. After March 20, 1903, all subscriptions must be paid directly to the General Secretary of the Congress at Madrid.

Article 5.—Every member of the Congress, at the time when he sends his subscription, should also forward to the General Secretary, either directly or through his national committee, a note clearly indicating his name and degrees, as well as his address, accompanied by his visiting card.

Article 6.—Members of the Congress who fulfill these conditions will have the right to take part in all the proceedings, to present communications, either verbal or written, to take part in the discussions, to cast a vote on all questions submitted for decision in that way, and to share in all of the privileges reserved for members of the Congress.

Article 7.—Besides this, they will receive a general summary of the proceedings of the Congress, and a full report of the work of the particular section which they join. Those members who desire to receive several volumes or the complete collection of reports, will be required to pay for each volume a sum which will be decided upon later, but which will not exceed the price of printing. Subscriptions for the volumes will be received by the General Secretary until the close of the Congress. Members who present written communications in several sections which are accepted by the committee that examines them, will receive the volumes of these sections without any further payment.

Article 8.—The reports will be sent to members just as soon as they are published.

Article 9.—The Congress will be divided into the following sections: (See Work of the Sections, below.)

Article 10.—The members of the Congress are requested, at the time they send their subscription, to indicate the section or sections to which they desire to belong. The members who are enrolled in several sections, will receive the volume of the first of the sections indicated.

Article 11.—To an executive committee, composed of the President, General Secretary, and Treasurer, and the Presidents and Secretaries of the sections, will be entrusted the management of the Congress.

Article 12.—The Congress will assemble every day, either in general session or in meetings of the sections.

Article 13.—There will be two ordinary general sessions, one for the opening and one for the closing of the Congress, and, in addition, as many special sessions as shall be thought necessary; their number will be decided upon by the executive committee. At these sessions addresses will be delivered by scientists of various nations, on invitation of the officers of the Congress, and there will be no discussions at these meetings.

Article 14.—In the opening session the General Secretary will give an account of the work of organization, the President will read the inaugural address, the official delegates will be presented, and the honorary Presidents will be announced. At the closing session a review of the deliberations of the Congress will be presented, the place of the next meeting will be announced, and the new officers will be elected. In these meetings only those members who have been designated and invited by the executive committee will take part in the discussions

Article 15.—The committees of the sections shall arrange the programs of their proceedings (the reading and discussion of the communications, the examination of the propositions presented, etc.). Each section shall, at its first meeting, nominate its honorary Presidents, and shall designate its assistant secretaries; a certain number of these shall be chosen from among the foreign members, to give a verbal résumé of the communications presented in the different languages, and thus to facilitate their discussion.

Article 16.—The President of each section shall direct the work of that section in the established form for all deliberative bodies. Only the questions pertaining to the management of the sessions shall be submitted to vote. Scientific questions shall not be voted upon.

Article 17.—The time assigned to each communication shall not exceed fifteen minutes, and the speakers who take part in the discussions will not be allowed more than five minutes; ten minutes will be granted the authors of the communications for closing the discussion. Exceptionally, and when the importance of the subject justifies it, the President may allow more time to the speaker. Any member who takes part in the discussions must send to the Secretary of the section, before the adjournment of the session, a short résumé of his remarks.

Article 18.—The communications referring to the proceedings of the Congress must be sent to the General Secretary before the first of January, 1903; he will attend to their transmission to the proper section. The titles of the communications should be accompanied by a short résumé in the form of conclusions, if possible; this abstract will be printed by order of the Executive Committee of the Congress and distributed to the members of the corresponding section.

Article 19.—Communications may be presented after the first of January, 1903, and even during

the Congress, but such will not be considered until after the discussion of those regularly announced.

Article 20.—The written text of all the works presented to the Congress, whether in the general assemblies or in the sections, should be sent on the same day to the Secretary of the respective committee. The Executive Committee shall decide upon its total or partial insertion in the reports.

Article 21.—The official languages of the Congress in all the sessions shall be English, French, German, Spanish, and Italian.

Supplementary Article.—Ladies belonging to the families of the members, and accompanying them, shall have the benefit of the reductions on the rail roads, and can take part in the various entertainments which are given in honor of the members of the Congress. For this purpose, they should provide themselves with a special card, the price of which is twelve pesetas.

General Addresses.

The following addresses will be delivered at the general sessions of the Congress: S. Laache of Christiania, on "Reciprocity in Pathology"; Ivan Petrovitch Pavlov of St. Petersburg (subject to be announced); Arthur Thomson of Oxford (subject to be announced); Wilhelm Waldeyer of Berlin, on "Phylogenic Theories and Darwinism"; Eduardo Maragliano of Genoa, on "The Struggle of the Organism against Tuberculosis"; P. Brouardel of Paris, on "Adulteration of Food"; A. Politzer of Vienna, on "The Necessity of the Official Teaching of Otology"; Rodriguez Carracido of Madrid, on "Pharmacological Complexity in Medical Prescriptions"; Santiago Ramón y Cajal of Madrid (subject to be announced); Rafael Rodriguez Mendez of Barcelona (subject to be announced); Howard A. Kelly of Baltimore, on "Urinary Infection"; Juán Santos Fernández of Havana, on "Diseases of the Eyes in the Tropics"; Emilio R. Coni of Buenos Ayres, on "Public Medicine in South America."

Work in the Sections.

I. **Anatomy** (Anthropology, Comparative Anatomy, Embryology, Descriptive Anatomy, Normal Histology, and Teratology).—*President*, Santiago Ramón y Cajal; *Secretary*, Dalmacio García Izcara.

Discussions: (1) What is the Best Method of the Didactic Exposition of the Nervous System? (2) Positive Value of Anatomical Measures for the Ethnical Determination of Individuals. This discussion will be opened by Giuseppe Sergi (Rome); R. Live (Rome), and Manouvrier (Paris). (3) Structure of the Nerve Cell. Discussion opened by Camillo Golgi (Pavia), Romeo Fusari (Turin), and Holmgren (Stockholm). (4) Origin of the Fibroblasts in Connective-tissue New Growths, Normal and Pathological.

II.—**Physiology, Physics, and Biological Chemistry.**—*President*, Gabriel de la Puerta y Ródenas; *Secretary*, Juán Manuel Díaz del Villar.

Discussions: (1) The Physiological Action of Saccharin; Should Its Use in Food and Beverages Be Forbidden and Should It Be Employed Solely as a Therapeutic Agent? Discussion opened by Gabriel de la Puerta y Ródenas. (2) The Influence of Glandular Poisons on Muscular Contraction. Discussion opened by Enrique Pérez Zúñiga, Christiani (Geneva). (3) Biochemical Study of Organometalloid and Metallic Combinations. Discussion opened by Aúgustin Mura y Valerdi. (4) Experimental Pancreatic Glycosuria. Discussion opened by Juán M. Díaz del Villar, Pietro Albertoni (Bologna), Filippo Bottazzi (Florence).

III.—**General Pathology, Pathological Anatomy, and Bacteriology.**—*President*, Amalio Gimeno y Cabañas; *Secretary*, Antonio Mendoza.

Discussions: (1) Parasitism in the Formation of New Growths. Discussion opened by Marchiafava (Rome). (2) The Genesis of Sarcomata. (3) Blastomycetic Lesions. (4) The Desirability of a Revision of the Classification and Description of the Known Bacteria. Discussion opened by Antonio Mendoza, Bartolomeo Gosio (Rome). (5) Vaccinations with Chemical and Culture Liquids. Discussion opened by Alessandro Lustig (Florence).

IV.—**Therapeutics and Pharmacy.**—*President*, Benito Hernando y Espinosa; *Secretary*, Martín Bayod y Martínez.

(*a*) Therapeutics.—*Discussions:* (1) Relations between the Chemical Composition of Medicaments and Their Physiological Action. Discussion opened by Emilio Pérez Noguera, Brunton (London), Cervello (Palermo), Bardet and Robin (Paris). (2) The Dangers and Exigencies of the So-called Intensive or Exaggerated Medication in Chronic Diseases, and Chiefly in Tuberculosis. Discussion opened by Antonio Espina y Capo, Hayem (Paris). (3) Utility and Dangers of Intraspinal Injections of Cocaine in Medicine and in Surgery. Discussion opened by Francisco Pí y Suñer (Barcelona), Tuffier (Paris), Postempski (Rome). (4) Mechanism of the Physiological and Therapeutic Action of Hypnotics and Narcotics. Discussion opened by Vicente Peset y Cervera (Valencia), Vincenzo Chirone (Naples). (5) Intravenous Therapy. Discussion opened by Rossoni (Rome), Gaetano Rummo (Palermo). (6) The Treatment of Tetanus by Baccelli's Method. Discussion opened by Agenore Zeri (Rome). (7) The Treatment of Epizoötic Aphthæ by Baccelli's Method. Discussion opened by Loriga (Rome).

(*b*) Medical Hydrology.—*Discussions:* (1) The Physicochemical Study of the New Gaseous Elements, Argon and Helium, in Mineral Waters. Discussion opened by Ramón Llord y Gamboa, A. Poskin (Spa), Raymond Durand-Fardel (Paris), Vinaj (Turin). (2) Syphilis and Its Hydromineral Treatment. Discussion opened by Marcial Taboada, G. Soffiantini (Acquarossa), Hermann Keller (Rheinfelden). (3) Tuberculosis and Its Hydromineral Treatment. Discussion opened by Agustín Lacort, Marcellin Cazaux (Eaux-Bonnes). (4) The Qualitative and Quantitative Determination of Fluorine in Mineral Waters. Discussion opened by Llord y Gamboa.

(*c*) Pharmacy.—*Discussions:* (1) The Therapeutic Valuation of Antitoxic Serums. Discussion opened by Francisco de Castro y Pascual. (2) The Importance and Superiority of the Colloid State of Matter in the Preparation of Medicaments and in Their Pharmacological Action. Discussion opened by José López Capdepón. (3) Hypodermic Injections; Their Pharmaceutical Significance and the Desirability of Preparing a Pharmacopœia Unifying the Procedures for Making and Preserving These Preparations. Discussion opened by Emilio Alcobilla, Giovanni Bufalini (Florence). (4) The Necessity and Utility of Medicaments of Definite Therapeutic Action. Discussion opened by Manuel Alvarez Ude.

V.—**Internal Medicine.**—*President*, José Calvo y Martín; *Secretary*, Enrique Oliván y Sanz.

Discussionss: (1) Rôle of the Brain, Heart, and Kidneys in Infections. Discussion opened by José Codina Castellví. (2) Etiology and Prophylaxis of Paludism. Discussion opened by Francisco Huertas Barrero, Celli (Rome), Vittorio Ascoli (Rome). (3) Pathogeny of Cardiac Arrhythmia.

Discussion opened by Antonio Espina y Capo, Castellino (Naples). (4) Application to Clinical Medicine of the New Investigations Concerning the Physical and Chemical Properties of Blood Serum. Discussion opened by Lucatello (Padua). (5) Etiology and Therapy of Pellagra. Discussion opened by Devoto (Pavia). (6) Diet in Typhoid Fever. Discussion opened by Queirolo (Florence).

VI.—**Nervous and Mental Diseases, and Criminal Anthropology.**—*President*, José Maria Esquerdo y Zaragoza; *Secretary*, Abdón Sánchez Herrero.

Discussions: (1) The Toxic and Infectious Insanities. Discussion opened by Jerónimo Galiana. (2) Psychical Etiology and Therapeutics. Discussion opened by Sánchez Herrero. (3) The Center of Projection and Association in the Brain According to the Determinations of Exact Pathological Anatomy. Discussion opened by Bianchi (Naples). (4) The Clinical Study of Agnoscia and of Asymbolia. Discussion opened by Simarro y Lacabra. (5) The Delimitation of the Pathological Nature of Crime. Discussion opened by Rafael Salillas, Morselli (Geneva). (6) The Intervention of Psychiatry in the Reforming Treatment of Criminals. Discussion opened by Alonso Martínez, Lombroso (Turin).

VII. **Pediatrics.**—*President*, Francesco Criado y Aguilar; *Secretary*, Manuel Tolosa de Latour.

Discussions: (1) The Therapeutic Value of Orrhotherapy in Diphtheria. Discussion opened by Vicente Llorente y Matos, Comby (Paris), Cervesato (Bologna), Luigi Concetti (Rome). (2) Treatment of Club-foot. Discussion opened by Antonio Martínez Angel, Broca (Paris), A. Lorenz (Vienna), Ghillini (Bologna). (3) Treatment of Tuberculous Joints. Discussion opened by José Ribera y Sans, Lannelongue (Paris), Hoffa (Würzburg). (4) Infant Feeding. Discussion opened by Fernando Calatrareño; Rousseau Saint-Philippe (Bordeaux), Guaita (Milan).

VIII. **Dermatology and Syphilography.**—*President*, Manuel Sánz y Bombín; *Secretary*, M. Juán de Azúa y Suárez.

Discussions: (1) Gonorrhœa from the Medico-Social Point of View. Discussion opened by Suárez de Mendoza, Ernest Finger (Vienna), Bertarelli (Milan), Giuseppe Profeta (Geneva), Vittorio Mibelli (Parma). (2) Parasyphilitic Diseases; Retrospective Diagnosis of Syphilis. Discussion opened by Sanz Bombín, Augusto Ducrey (Pisa). (3) Treatment of Pruritus. Discussion opened by Juán de Azúa. (4) The Purpuras. Discussion opened by Juán de Azúa.

IX. **General Surgery.**—(*a*) Surgery and Surgical Operations.—*President*, Federico Rubio y Gali; *Secretary*, Ramón Jiménez y García.

Discussions; (1) Post-Operative Deaths. Discussion opened by Ribera, Davide Giordano (Venice), Domenico Biondi (Sienna). (2) Indications for Surgical Intervention in Affections of the Stomach. Discussion opened by Cardenal (Barcelona), Novaro (Geneva), Ceccherelli (Parma), Hartmann (Paris).

(*b*) Urology.—*President*, Alfredo Rodríguez Viforcos; *Secretary*, Luis González Bravo.

Discussions: (1) The Remote Results of Surgical Intervention in Malignant Tumors of the Kidneys. Discussion opened by Mollá (Valencia), Azcarreta (Barcelona), Pousson (Bordeaux), Mariani (Geneva). (2) The Comparative Value of the Means Actually at Our Disposal for the Appreciation of the Functional Condition of the Kidney. Discussion opened by González Bravo, Lobo Regidor, Albarrán (Paris), Giuseppe Mya (Florence), Casper and Richter (Berlin).

X. **Ophthalmology.**—*President*, Santiago de los Albitos; *Secretary*, Francisco Sanz y Blanco.

Discussions: (1) The Surgical Treatment of the Affections of the Lacrymal Passages. Discussion opened by Castresana y Goicoechea, Reymond (Turin), Tartuferi (Bologne) Lapersonne and Rochon-Duvignaud (Paris). (2) The Necessity of Unification of Optometric Scales. Discussion opened by Jacinto de las Cuevas y Pulido, Landolt (Paris). (3) Optic Neuritis in the Course of Acute Affections. Discussion opened by Francisco Sanz y Blanco, Vincenti (Naples), Antonelli (Paris). (4) Investigations Concerning the Action of Medicaments on the Pupil, the Accommodation and Intraocular Tension. Discussion opened by Manuel Márquez Rodríguez.

XI. **Oto-Rhino-Laryngology.**—(*a*) Otology.—*President*, Juan Cisneros y Sevillano; *Secretary*, Rafael Forns y Romans.

Discussions: (1) The Causes of Deaf-Mutism. Discussion opened by Verdós (Barcelona), Castex (Paris), Schmiegelow (Copenhagen). (2) The Anatomical and Clinical Study of Cholesteatoma. Discussion opened by Luciano Barajas, Schwartze (Halle), Cozzolino (Naples). (3) The After-treatment of Operative Procedures on the Ear. Discussion opened by Botey (Barcelona), Lermoyez (Paris), von Stein (Moscow).

(*b*) Rhino-Laryngology.—*President*, Eustasio Uruñuela; *Secretary*, Celestino Compaired.

Discussions: (1) Is Surgical Intervention in Every Kind of Laryngeal Cancer, and in All Its Phases or Periods Desirable from the Medico-Social Point of View? Discussion opened by Sota y Lastra (Seville). (2) The Valuation of Local Treatment of Laryngeal Tuberculosis. Discussion opened by Roquer Casadesús (Barcelona), Krause (Berlin), Grazzi (Florence), Masini (Geneva). (3) Is Atrophic Rhinitis Always of Autochthonous Nature? The Necessity of Establishing an Exact Diagnosis in Order to Determine Its Treatment. Discussion opened by Peláez (Granada), Moure (Bordeaux), Freudenthal (New York).

XII. **Odontology and Stomatology.**—*President*, Alejandro San Martin; *Secretary*, Florestán Aguilar.

Discussions: (1) The Treatment and Filling of Teeth Having Diseased Pulps. Discussion opened by A. V. Harlan (Chicago), J. D. Losada. (2) Dental Microscopy. Discussion opened by Leon Williams (London), J. Choquet (Paris). (3) Bucco-Facial and Skeletal Prosthesis. Discussion opened by Claude Martin (Lyons), V. Guerini (Naples), Delair (Paris). (4) The Requirements that Ought to Be Insisted Upon for the Practice and Teaching of Odontology. Discussion opened by Godon (Paris), Florestán Aguilar. (5) The Nature and Treatment of Alveolar Pyorrhœa. Discussion opened by Hopewell Smith (London), Younger (Chicago), Damians (Barcelona). (6) Local Anæsthesia in Odontology. Discussion opened by C. Amoedo (Paris), Pier Michele Giuria (Geneva).

XIII. **Obstetrics and Gynecology.**—*President*, Eugenio Gutiérrez González; *Secretary*, Carmelo Carrillo y Cubero.

Discussions: (1) Indications for Hysterectomy in Acute Puerperal Infection. Discussion opened by J. Cortiguera (Santander), Pinard (Paris). (2) The Treatment of Placenta Prævia. Discussion opened by Candela (Valencia), Pestalozza (Florence), Leopold (Dresden). (3) The Pathogeny and Treatment of Chronic Cellular and Peritoneal Inflammations of the Pelvis. Discussion opened by Martín Gil (Malaga), Doléris (Paris). (4) The Indications and Results of Opotherapy in Gynecology. Discussion opened by Jayle (Paris). (5) The Conservative

Surgery of Lesions of the Adnexa. Discussion opened by Fargas (Barcelona), Treub (Amsterdam), Palmer Dudley (New York), Mangiagalli (Pavia).

XIV. **Military and Naval Medicine and Hygiene.**—*President*, Antonio Serrano y Borrego; *Secretary*, Hermenegildo Tomás del Valle.

Discussions: (1) The Way to Solve the Tuberculous Problem in Armies. Discussion opened by Traller. (2) The Advantages and Disadvantages of Compressed Medicaments in Campains. Discussion opened by Ubeda y Correal, Mazzoni (Rome). (3) The Influence of Military Life on the Development of Affections of the Nervous System, Particularly Insanity. Discussion opened by Salinas. (4) Hygiene of Troops on Sea and Land on the West Coasts of Africa. Discussion opened by Angel Fernández-Caro. (5) Prophylaxis of Syphilitic and Venereal Affections in the Army. Discussion opened by Rodríguez Vázquez, Favre (Rome). (6) Sick Wards on Modern Ships. Discussion opened by Redondo, Francisco Coletti (Rome).

XV. **Hygiene, Epidemiology, and Technical Sanitary Science.**—*President*, Félix Guzmán y Andrés; *Secretary*, Felipe Ovilo y Canales.

Discussions: (1) The Necessity of Determining the Prophylactic Value of Disinfection and the Methods Generally Followed. Discussion opened by Angel Fernández-Caro, Canalis (Geneva). The Practical Means, Individual and Collective, of Preventing the Spread of Dysentery. Discussion by Larra y Cerezo. (3) The Desirability of Establishing Sanitary Custom-Houses on the Land Frontiers of Countries. Discussion opened by Guzmán Andrés, Pagliani (Turin). (4) The Utility of Tuberculosis Dispensaries as a Means of Increasing Vital Resistance in the Poorer Classes. Discussion opened by Montaldo Peró, Sclavo (Sienna). (5) Hygiene and Sewage. Discussion opened by Menéndez Novo, Rosario Bentivegna (Rome).

XVI. **Forensic Medicine and Toxicology.**—*President*, Adriano Alonso Martínez; *Secretary*, Julián Fuentes Fernández.

Discussions: (1) The Legal Significance of Wounds According to Their Cause, Situation, and Character. Discussion opened by Gian Giacomo Perrando (Sassari). (2) The Medicolegal Concept of Deformities. (3) Discernment and Precocious Criminality. Discussion opened by Fuentes, Tamassia (Padua). (4) The Capacity and Responsibility of Degenerates. Discussion opened by Alonso Martínez, Alberto Severi (Geneva). (5) Concerning the Localization of Poisons. Discussion opened by Mariscal.

HOW TO GET TO MADRID.

It is, of course, possible to reach Spain, sooner or later, by any line of steamers crossing the Atlantic, but if one's time is limited his choice of steamers will be considerably narrowed. Practically the only lines available are those to the Mediterranean direct and those whose steamers call at one of the French Channel ports, and perhaps the American line to Southampton.

Mediterranean Steamers.—The *Spanish Transatlantic Line*, Pier 10, East River, New York. Steamers of this line sail the third of each month for Cadiz and Barcelona. Fare: first cabin, $100 to $130; second cabin, $75 each way; round-trip tickets are issued at 25 per cent. discount. There is a further reduction of 33 per cent. granted to members of the Congress. The *Insular Navigation Company*, Atlantic Dock, Brooklyn. Steamers sail from New York every three weeks for Lisbon. Fare, $75, with 10 per cent. reduction on round-trip tickets. From Lisbon one can go to Cadiz or Gibraltar by water, or to Madrid direct by rail in about thirty-three hours. The *German Mediterranean Express Service.* Steamers of the North German Lloyd for Gibraltar sail from Pier 26, foot of Congress street, Brooklyn; those of the Hamburg-American from the Company's piers, foot of First street, Hoboken. Fare, $80 or $85 to $150, with 10 per cent. reduction on round-trip tickets. No deduction is made for members of the Congress, but they will be given some advantages in the way of better location. The *Dominion Line* from Boston to Gibraltar direct. Fare: first cabin, $60 to $100 and up; second cabin, $50 and $60; reduction on round-trip tickets 10 per cent. off the price of the return ticket. There will probably be a special steamer of this line despatched to Gibraltar for the accommodation of those going to the Congress.

Steamers to the Channel Ports.—The *Holland-American Line*, pier foot of Fifth street, Hoboken. Steamers sail every Wednesday to Rotterdam, calling at Boulogne-sur-Mer, France. Fare: first cabin, $60 to $75 and up—round trip, 10 per cent. reduction on both going and returning; second cabin, $40 to $50 and up, round trip 10 per cent. reduction on return ticket only. Members of the Congress will be given special advantages in the matter of location. The *French Line*, Pier 42, foot of Martin street, North river. Steamers sail every Thursday for Havre. Fare: first cabin, $60 to $130—round-trip, $108 to $234; second cabin, $40 to $46—round trip, $76 to $87. *Hamburg-American Line*, pier foot of First street, Hoboken. Steamers sail several times a week to Hamburg, stopping at Plymouth, England, and Cherbourg, France. Fares: first cabin, from $60 to $200, according to ship and location of berth; second cabin, $45 to $60 and up; round-trip tickets, 10 per cent. reduction on the return fare. *North German Lloyd.* Steamers sail from New York on Tuesdays and Thursdays for Bremen, stopping at Southampton, England, and Cherbourg, France. Fares: first cabin, $80 to $100 and up, according to steamer and location of berth; second cabin, $45 to $60; round-trip tickets, 10 per cent. reduction on the return ticket. *American Line*, Pier 14, North River. Steamers sail every Wednesday for Southampton, calling at Cherbourg on the return, but not on the outward passage. Fare: first cabin, $90 to $100 and up—round trip, 10 per cent. off the combined fares; second cabin, $40 up, round trip 10 per cent. off the return fare.

All these steamers, except those of the American Line, land their passengers within four or five hours by rail of Paris. From Paris to Madrid, a distance of 899 miles, is a journey of thirty-two hours by the ordinary express, and of twenty-eight hours by the limited express (*train de luxe*). Fares: first class, 165 francs ($33); second class, 115 francs ($23); on the limited express, first class only, 247 francs ($49.50).

Nearly all the railways of France and Spain offer a reduction of 50 per cent. to members of the Congress, on round-trip tickets. The central committee of Europe having in charge the interests of the Congress has named the *Voyages Pratiques* of Paris as the official agency to make all arrangements for the transportation and lodging of those attending the Congress, and to organize and conduct a series of tours through Spain. The regular trains being few in number and apt to be over-crowded, it has arranged for a number of special trains, but since places in these will be filled early, those who expect to attend the Congress should make their applications as soon as possible, to insure accommodations. This is especially advised owing to the extreme difficulties of travel in Spain, and the over-crowding

and irregularities which may occur unless proper precautions are taken. The *Voyages Pratiques* is enabled to offer members the advantage of 50 per cent. reduction on the railways, for round-trip tickets. In order to facilitate the arrangements of the American physicians who expect to attend the Congress, the *Voyages Pratiques* has appointed the tourist firm, Dr. and Mrs. Howard S. Paine of Glens Falls, N. Y., as its American representative, with full authority to act for it in all the capacities enumerated above. Half-fare tickets may also be obtained through Thos. Cook & Son at any of their American offices. In order to take advantage of these reduced rates one must show his card of membership when purchasing the tickets. The tickets are valid for the journey to Madrid from April 1, and for the return trip until May 15.

The principal hotels in Madrid are Hotel de Paris, de la Paz, de Rusia, de Roma, Inglés, de los Embajadores, Quatro Naciones, Peninsular, Oriente, and Santa Cruz. The rates vary according to the hotel and the accommodations; the first named are the most expensive, the charge for room and board running from about $4 to $6 a day; the rates at the cheap hotels run from $2 to $3.50 a day. There are many boarding-houses in Madrid at which the rates are from $1.50 to $2 a day. The accommodations for travelers in Madrid are limited, and it will be well to engage room and board in advance. Those desiring to do so should apply to the Bureau des Logements, Facultad de Medicina, Madrid, using for the purpose a blank to be obtained from the American Secretary, Dr. Huddleston, and enclosing a deposit of fifty francs ($10).

Money for the subscription to the Congress or for deposit for board may be sent by express money order, or by check through the tourist agency of Thomas Cook and Son, 261 Broadway, New York. The U. S. Post-Office issues no money orders for cities in Spain.

A Short Tour in Spain.

Spain lies somewhat apart from the ordinary tourist track, and is for that reason comparatively seldom visited. Probably few of the physicians who will be present at the Congress would ever have visited the country had they not been drawn there by this event, and few of them will ever have the opportunity or the excuse to visit it again, and it will therefore be well worth their while when once in Spain to see more of it than is contained in Madrid alone. Though so infrequently visited, there is more in Spain that is worth seeing than in almost any other country of Europe, Italy alone excepted. Saragossa, Terragona, Valencia, Alicante, Málaga, Cadiz, Seville, Córdova, Granada, Toledo, and Barcelona are all full of interest to the lover of pictures or architecture, or to one who likes the picturesque and to study the customs of a people. If one's time is limited, however, it will be better not to attempt to visit so many places, but Córdova, Seville, and Granada should on no account be missed. They can easily be visited on the way to Madrid, if one lands at Cadiz or Gibraltar, but a special trip will have to be taken if the visitor to the Congress enters the country from the north, or reaches Madrid by way of Barcelona.

Supposing that the traveler starts from Madrid, and has at his disposal seven or eight days either before or after the Congress, he can in that time see the three cities mentioned, spending one day in Córdova, two in Granada, and three in Seville. The necessary expenses for the trip, if one travels first-class on the railways and puts up at the best hotels—advisable even for men, unless they are good Spanish scholars and familiar with the customs of the country, and practically necessary if there are ladies in the party—will be about $65. There will probably, however, be special railway rates for members of the Congress, thus reducing the absolutely necessary expenses to about $40 or $50.

Córdova.—Leaving Madrid in the evening by the express, with sleeping-cars attached, running on Monday, Wednesday, and Friday, we arrive at Córdova, 270 miles distant, twelve hours later. (Express trains in Spain, be it said, are rapid only by comparison, the swiftest never exceeding twenty-five miles an hour. From ten to fifteen miles an hour is the ordinary pace, and even then the traveler arrives late at his destination more often than not.) The best hotels are the Oriente, the Suiza (or Hôtel Suisse), and the Española. Here, as well as elsewhere, it will be advisable to have a definite understanding as to prices before taking a room. A stay of one day will suffice for Córdova, if one is pressed for time, but two or three days, if available, can be pleasantly spent here.

The chief attraction of Córdova is the cathedral, formerly a mosque, one of the sights of the world. It was built between 786 and 990 A.D. by the Moors, and as an example of Arab architecture it is said to be excelled in magnificence only by the mosque at Mecca. Other sights of the city are the Alcázar, the Episcopal Palace, the Triunfo, a marble monument with a bronze statue of the angel Raphael, and a Moorish bridge, spanning the Guadalquivir river, which rests upon Roman foundations attributed to Octavius Augustus.

Granada.—From Córdova we go by train (153 miles in ten hours) to Granada, via Bobadilla, where one gets a fair meal. The majority of English and American tourists go to the Hotel Washington Irving or the Hotel Siete Suelos in a pleasant park close to the Alhambra. Other somewhat less expensive hotels in the town are the Victoria and the Alameda. Two days at least should be devoted to Granada, the chief attractions of which are the cathedral and the incomparable Alhambra, the palace of the Arab rulers of Southern Spain.

Seville.—In order to reach Seville from Granada we must go back by the road we came as far as Bobadilla. The distance from Granada to Seville is 180 miles, which the express trains cover in twelve to fourteen hours, unless they meet with unusual delay. The best hotels are the Madrid, the Paris, and (less expensive) the Roma. Seville is one of the most delightful cities in Spain, and is worthy of a long visit; the most hurried tourist should give at least three days to it. The chief attractions are the magnificent gothic cathedral and the Alcázar, formerly the palace of the Moorish kings. The Alhambra at Granada, the Mosque at Córdova, and the Alcázar at Seville are the three most beautiful examples of Moorish architecture in Spain. Seville is celebrated for the magnificence of its church services in Holy Week, which surpass those of Rome itself. The tourist whose time is limited had, however, better avoid the city during the last three days of Lent, for the crowd is then very great, and it is quite impossible to do any ordinary sight-seeing. Easter this year falls on April 12.

From Seville one may go back to Madrid by night express train, leaving on Tuesday, Thursday, and Saturday, and covering the distance in fifteen hours. If there is time, one may go to Cadiz from Seville by river steamer or by rail, and from Cadiz steamers sail at frequent intervals for Tangier (an interesting but terribly dirty place), and for Gibraltar, Málaga, and Barcelona.

Toledo.—This most interesting town, which has

been well called "an open-air museum of the architectural history of early Spain," is distant only two hours by rail from Madrid, and should, by all means, be visited, even if one has no time to go to the cities above named. The main attraction is the cathedral, the seat of the Metropolitan Archbishop of Spain; but the city itself and everything in it are most interesting.

The **Escorial,** thirty-one miles from Madrid, may be visited in one day. It is the seat of the monastery of San Lorenzo, called by the Spaniards the eighth wonder of the world. This was built by Philip II, and contains the tombs of all the Spanish monarchs who have died since his time.

In **Madrid** the rich art treasures of the museum will repay all the time that can possibly be spared to the study of them. It contains no less than sixty-four masterpieces by Velasquez, and forty-six by Murillo, besides many pictures by Rubens, Van Dyck, Guido Reni, Raphael, Titian, Tintoretto, Paulo Veronese, and other Spanish, Dutch, and Italian masters. In the *Real Academia de Bellas Artes* there is another collection of some three hundred by Murillo, Rubens, Zurbarán, and others. The *Museo de Arte Moderno*, like the Luxembourg of Paris, contains the works of modern painters and sculptors of the country. There are many things here to repay a visit. The *Palacio Real*, Royal Palace, contains much of interest in the way of tapestries, statues, and magnificent decorations. The fresco by Tiepolo in the Sala de los Embajadores or Throne Room represents the exaltation of the Spanish monarchs. The Armeria contains an interesting collection of armor and weapons of various kinds, among which is the reputed sword of the Cid.

One of the places that will no doubt be visited by most of the Congress members is the Bull Ring or *Plaza de Toros*, which is one of the largest in Spain, seating over 14,000 persons.

Personally Conducted Tours.—Several special tours in Spain are being arranged for in connection with the Congress. The expense of these varies according to the length of the tour and the route followed, but in every case there will be an appreciable saving over the cost of individual travel, to say nothing of the saving of annoyance, especially to those unfamiliar with Spanish. The fares include first-class railway and steamship travel throughout, especially reserved hotel accommodations with meals from the time of arrival in Spain until the departure therefrom, transfer of passenger and baggage between stations and hotels, fees to hotel servants, porters, etc., and the services of a competent conductor from the time of arrival to the sailing of the steamer for America. One-day excursions to Toledo and to the Escorial are also planned for the Congress week, and the days immediately preceding and following it.

The following are the names of the persons interested in promoting these tours, who will be glad to give full particulars upon request: Mr. A. V. D. Honeyman, President and Treasurer of the New Jersey Law Publishing Co., Plainfield, N. J.; Dr. Charles Wood Fassett, Managing Editor of the *Medical Herald*, St. Joseph, Mo.; Dr. Ramón Guitéras, 75 West Fifty-fifth street, New York City; and Dr. and Mrs. H. S. Paine, 148 Ridge Street, Glens Falls, N. Y., representatives in the United States of *Les Voyages Pratiques* of Paris.

Visitors to the Congress should provide themselves with passports. These are not required for admission to the country, as in Russia, but in case of need and as a means of identification, they will be found very useful.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, Held January 15, 1903.

ROBERT F. WEIR, M.D., PRESIDENT.

Annual Reports.—The reports presented showed that there had been added to the membership of the academy during the past year twenty-eight resident and nine non-resident members. The total accessions to the library were 1,026 bound volumes. In 1902 no less than 12,406 readers registered in the library. Since 1894 there had been an increase of over 100 per cent. in the number of those using the library.

Address of Retiring President.—Dr. ROBERT F. WEIR, in retiring from the chair, presented a brief review of the condition of the academy. He said that two years ago, on taking office, there were 774 resident members, and he was sorry to say that this number had not been very materially increased, the present membership being only 789. He had hoped that before this it would have been found possible to let down the bars, and reduce the dues, so that many of the young and struggling members of the profession could be admitted. It was found, however, that the needs of the academy absorbed nearly all of the present income, so that this interesting problem must be left for his successors to solve.

The Surgical Presidents of the Academy.—Dr. WEIR then commented upon the comparatively small number of surgeons who had been honored by election to the presidency of the academy, and gave a brief sketch of them. The first of the surgical presidents, he said, was Valentine Mott, justly regarded as the most eminent of American surgeons. He was a distinguished looking man, and was neatness personified. He died in 1865 of thrombotic gangrene of the leg. His estate was valued at over one million of dollars, and yet his maximum fee was $1,000, and was received on only two occasions. This was in striking contrast with the inflated fees of the surgeons of the present day. His successor was the noted surgeon, Dr. Alexander H. Stevens. He was a very impressive teacher, and was always spoken of by his colleagues with the deepest respect. Dr. Willard Parker, the third of the surgical presidents, was elected in 1856. He was a worthy man, of magnificent physique and impressive manner; he was a good surgeon, but a better teacher. Though rest and diet made up the greater part of his remarks, his teachings bore good fruit. The month after his graduation, in 1830, he was lecturing on anatomy in the college. In 1839 he succeeded Dr. Stevens in the Chair of Surgery at the College of Physicians and Surgeons. Dr. Parker was the first to operate upon appendicitis, and also to discard splints in the treatment of Colles' fracture and substitute a band of adhesive plaster. Dr. John Watson was the next one on the list. He was an irritable man, with great learning and less knowledge, but he was a just and kind man, and was zealous and faithful in the performance of his professional duties. Next came Dr. Alfred C. Post, a wise and very industrious man, so upright in character that some said he bent backward. His labors never ceased, and his interest was as great in small as in large things. The last of the list was Dr. Joseph D. Bryant, who was elected in 1895, and who is still living, and well known to the present members.

Inaugural Address: The Young Practitioner.—Dr. ANDREW H. SMITH delivered this address. He said that, with his old friend, Dr. Weir, he had watched for two-score years the life of the academy. The kindness that he had always received from his colleagues, and particularly in his early days, had led him to take special interest in the young practitioners. It could be said truly that any man who had been properly educated, and who would work diligently along the lines to be laid down, could achieve a reasonable success in the medical profession, and better

than the average man going into business with a moderate capital. Brilliant successes were few, but, on the other hand, absolute failures were extremely rare. The young practitioner would do well to remember the advice, to open an office in a locality in which the poor would not be afraid to go, and the rich would not be ashamed to be seen. He should be just as careful in the treatment of the poor, charity patient as of the person paying the maximum fee. While attentiveness in the course of a serious illness was appreciated, it should not be forgotten that attentiveness too long kept up was also bound to be "appreciated." When a physician was asked how long a prescription just given was to be kept up, he should take it as a gentle hint that daily visits were no longer welcome, and should understand, also, that already he had lost some respect in the eyes of his client. The early years of practice were the time for note-taking. Even if never looked at afterward the notes should be taken, because the habit was, in itself, of great value. The period of waiting for private practice afforded an opportunity for attending the meetings of medical societies. These meetings not only taught the young man many things, but brought him into contact with others in the profession. This period was the one in which one naturally selected a specialty, if so inclined. The specialist who never stole a patient and confined his work strictly to his specialty would, in time, find his services in demand in proportion to the strictness with which this rule was observed. There was such a thing, however, as acquiring a practice too quickly. Some of the worst failures in practice he had ever known had resulted from young men securing a large business before they were fully equipped for such work. It was better, therefore, to grow into a practice than to fall into one. The interest of the patient should always be placed before your own, and the physician should be true to the best principles. His own judgment was against the formation of partnerships in medical practice, for conflict of opinion and interests was inevitable sooner or later. Lastly, he would say that every young practitioner in this city should join the Academy of Medicine as soon as he felt that he could do so without too great a financial sacrifice; until then he would be welcome, thrice welcome to the privileges of the academy, without money and without price. In time he would surely become one of those who helped to bear the burden that rightly went with membership.

Cardioptosis and Its Association with Floating Liver.—Dr. Max Einhorn read this paper. Although a comparatively new subject, a number of writers, chiefly foreign, had already reported several cases of movable heart. Associated with this condition were well-pronounced nervous symptoms, such as cardiac palpitation, fainting spells, tachycardia, bradycardia, and inability to lie on the left side. Cardioptosis signified a sinking of the heart from its normal position, due to a relaxation of its supports. There was no relation to the much more common condition of enteroptosis. Some writers differentiated between cardioptosis and movable heart. Cases in which the heart sunk below the fifth interspace without being enlarged were considered to be examples of cardioptosis.

The speaker said that he had recently examined carefully over 900 patients for cardioptosis, and had found this condition present in twenty-two persons, eighteen men and four women. This gave a total percentage of 2.4, or 3.5 among males and 1 per cent. among females. Enteroptosis and neurasthenia seemed to be contributory factors in the production of cardioptosis, but were not sufficient in themselves. The small number of cases occurring in women might, perhaps, be explained by the action of the corset in crowding upward the contents of the thorax. He had usually found in cases of cardioptosis an increased mobility of the heart. For instance, in the right lateral position, the apex of the heart would sometimes disappear altogether, whereas in others there was a considerable variation in the position of the cardiac apex. Cardioptosis was not a menace to life. The main objects of treatment were to increase nutrition and improve the tone of the nervous system. Of course, in addition, attention would be given to the removal of all causes tending to displace the heart.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held January 19, 1903.

Alexander Lambert, M.D., President.

A Small Dermoid Cyst.—Dr. J. Riddle Goffe presented a dermoid cyst, which had been removed from a woman, twenty-one years of age. She had a rachitic pelvis, but was otherwise fairly developed. Convulsions came on at the time of the establishment of the menses, and ultimately she developed epilepsy. This patient was also subject to the development of keloid upon slight injury. On performing laparotomy the uterus was found to be small and poorly developed, and the left tube and ovary, together with the dermoid cyst, were removed. Since the operation there had been no return of the epileptic fits. She had menstruated once since the operation, that time naturally and without pain; however, at the menstrual period, due in December, there was much pain without any flow. On examination at that time the ovary on the right side appeared to be very much enlarged, and surrounded by adhesions. Another laparotomy was done, and this revealed the fact that the right ovary was enlarged to four or five times its normal size, and was filled with cysts and hemorrhages. The ovary was removed.

Fibroid Tumors.—Dr. Goffe also presented two fibroid tumors. The smaller tumor was removed from the fundus of the uterus by myomectomy. The patient was a young woman, who had been married about one year, and had had a miscarriage at three months, probably as a result of the presence of the tumor. The omentum was adherent to the top of the tumor. While removing the latter from the fundus of the uterus, the uterine cavity was entered. This opportunity was seized for curetting the uterus, and introducing iodoform gauze through the opening down into the uterus and vagina for drainage. The woman made an uninterrupted recovery. The speaker said that the present practice was in favor of doing a myomectomy, even if it were necessary to remove a dozen tumors.

The larger tumor was removed from a woman, forty-five years of age, who had been married many years, and had borne a number of children. She had suffered for several years from hemorrhages, and had been treated for these by her physician by curettage. The condition of the interior of the uterus showed how futile was curettage in such a case, for it presented an immense fibroid polypus. The tumor was removed by laparotomy and supravaginal hysterectomy was done, and the stump covered over with peritoneal flaps, according to Dr. Goffe's method, as described by him in 1890.

Dr. George Tucker Harrison asked if it would not have been a better operation to dilate the uterus, bring down the polypoid mass, and deliver it through the vagina. In his opinion this would have been a perfectly feasible operation.

Dr. Goffe replied that the cervix was very long, and the passage of the sound had not revealed the fact that the tumor was a submucous one. But, in addition to the polypus, there were several irregular masses protruding into the peritoneal cavity; hence, the operation done seemed to have been a proper one. He knew of a similar case in which a surgeon had attempted to remove such a polypus through the natural passages, but had met with such great difficulty that the operation had to be abandoned, and the woman became septic afterward, and died from that complication.

A Hydrocele Removed Intact.—Dr. Parker Sims presented a hydrocele, which had been removed without

opening the sac. As it was loculated it showed how futile was the treatment by injection. The operation was very easy of performance.

Report of a Case of Acute Septicæmia; Intravenous Injection of Formalin; Recovery.—Dr. C. C. Barrows presented this report. The case occurred in Ward 23 of Bellevue Hospital, during Dr. Polk's absence. The patient was a negress, twenty-six years of age, and married. She was in labor at the time of her admission, and was having a chill. Her respirations were 30, and there was a fetid, bloody discharge from the vagina. She was delivered the following morning of a macerated fœtus, corresponding to about the development of the sixth month of pregnancy. After the delivery of the secundines she was given a douche of a one in ten thousand solution of bichloride. One hour later there was a severe chill, accompanied by a rise of temperature. At 3 A.M. the temperature was 99° F., and at 7 A.M. it was 108°. At 2 P.M. the uterus was irrigated with hydrogen dioxide, followed by two quarts of normal saline solution. A considerable quantity of blood clots and shreds of tissue was removed. She was then transferred to the gynecological service and was curetted. A large quantity of decomposed membranes and placental tissue was removed. She showed at this time marked evidences of sepsis. On the day of admission, a blood examination showed an absence of the malarial plasmodium and of leucocytosis. On December 30 a blood culture, made by Dr. Buxton, showed a pure culture of streptococcus. The urine contained albumin. It was at this time that Dr. Burrows first saw the woman. Her temperature was 108° F., the pulse 160 and over, and the respirations 38. She appeared to be dying. She was at once given 500 c.c. of a 1 to 5,000 aqueous solution of formalin. In three hours her temperature fell to 102°, and in six hours to 101°, and the pulse to 104, and the respirations to 28. After three hours the temperature gradually rose to 103°, and after three hours more it fell to 95° in the rectum. In twelve hours the pulse was 100 and the temperature 102°. The temperature then dropped to normal, and again rapidly rose to 103°. A second infusion of 750 c.c. of the same formalin solution was given. This was followed by a slight chill without a further rise of temperature, and, in the course of twelve hours, the temperature fell to the normal and, with one exception, had practically remained at this point ever since. The patient was now up and around the ward, and appeared to be entirely well. Several blood cultures had been made in this case, but none since the first infusion had shown the presence of any streptococci. Frequent microscopical examinations of the blood had been made, and no change in the blood-corpuscles had been discovered. The albumin had disappeared from the urine.

Commenting upon the case, the speaker said that formaldehyde seemed to him the most reasonable antiseptic agent to inject into the system. At the time of adopting this treatment, in the case just detailed, he had not been aware of the scholarly paper published in December, 1900, in the *Lancet* by Dr. R. McGuire; he was only cognizant of the fact that the physician at the Loomis Sanitarium had experimented with this agent in pulmonary tuberculosis. Dr. McGuire concluded that formaldehyde, in a dilution of 1 to 200,000 was a very efficient germicide, and that the maximum strength should be 1 to 2,000, or its equivalent, a 1-to-800 solution of formalin. In the case just reported, every effort had been made to eliminate the personal equation. The whole question rested upon this problem: Can a germicide be injected into the blood which will destroy the streptococcus and not injure the patient? Apparently formalin solution of proper strength was capable of doing this.

Other Cases.—Dr. Waitzfelder reported a similar case at the request of Dr. Silver, apologizing for the record's not yet being complete The patient was a woman. of twenty-six years, a primipara, who had been brought to the Gouverneur Hospital on December 28, 1902, with a history of having been confined three weeks before, and a few days thereafter developing symptoms of sepsis. Since then she has grown steadily worse. On admission she presented the ordinary symptoms of sepsis. Two days before, according to the history, a physician had curetted her with a blunt curette. At the time of her admission the temperature was 102.5° F., the pulse was 120 and the respirations 26. A considerable quantity of detritus was removed along with blood clots. On December 29 the temperature rose to 103°, and the next day to 105.5°. On December 31 the temperature was 104°, and on January 1 it again rose to 105°. When first seen by the speaker, on January 2, the temperature was 104.75°, the pulse was 120, and the respirations 26, and her physical condition was very bad. The uterus was again curetted, this time with a sharp curette, and it was then swabbed out with pure carbolic acid, with the idea of sealing up the lymph channels. Large doses of salines were then prescribed, according to the method of Lawson Tait. She grew steadily worse, so that on January 11 the temperature was 104°, and on the 13th was 105.5°. All hope of her recovery had been abandoned when Dr. Silver advised hypodermoclysis. An injection of 750 c.c. of normal saline solution were accordingly given. At that time her temperature was 105.5°. Within twelve hours the temperature fell to 96.25°, and with it there was a marked fall in the pulse rate. The next morning, that is, January 11, the temperature again rose to 103.5°. She was given 500 c.c. of normal saline solution by hypodermoclysis. The temperature fell from 105° to 102°. On the seventeenth day of the disease the temperature rose to 105.75°. She was given 750 c.c. of saline solution, which was followed after a short time by a fall of temperature. Twenty-four hours later the temperature was 105.5°. She received another injection of 500 c.c., which was followed by a fall of temperature of three degrees. On the evening of January 15 the speaker said he had first learned of Dr. Barrow's use of formalin, so 750 c.c. of a 1-to-5,000 solution of formalin were given to his patient. Within twelve hours the temperature fell from 104.5° to 96.75°. In twelve hours it rose to 105.5°, and remained at this point for twenty-four hours. On January 17 an effort was made to give an intravenous injection of what was supposed to be a 1-to-5,000 solution of formalin, but it was found subsequently that, through an error, the strength of the solution was really 1 to 2,500. After she had received about 100 c.c. of this strong solution she became cyanosed, passed into a condition of collapse, and appeared to be moribund. However, she was resuscitated, and a normal saline infusion was given with exactly the same result as had followed from the first injection of the formalin solution. This afternoon, or forty-eight hours after the last intravenous injection, her temperature was 101°, the pulse 120, and the respirations 48. The pulse was of fairly good volume. The speaker said he would like to draw attention to the fact that a remarkable change in the patient's condition had followed the use of normal saline solution, and that exactly the same result had been observed from the intravenous injection of formalin solution. While admitting the incompleteness of his record, he found it difficult to escape the conviction that the fall in temperature in his case was not due to the germicidal action of the formalin, but to the throwing into the circulation of a quantity of aqueous fluid, thus following out Tait's method of "washing out the germs." Moreover, examinations of the blood of his patient indicated that the hæmoglobin had been reduced in quantity after the injections, that the red blood-corpuscles were shrunken, and that the whole appearance of the blood was totally different from that observed after simply injecting a watery fluid into the circulation. Prior to carrying out the treatment the blood had been examined by Dr. Schulze of Cornell University, and it had been found to contain numerous streptococci.

Dr. W. L. Baner reported a case which had occurred in

the service of Dr. Biggs at St. Vincent's Hospital. The patient was a married woman, forty-two years of age, who, on December 1, had been struck upon the head with a cuspidore, and had received a small scalp wound. This had healed readily. A few days later she became ill with a cough and fever. On December 12 she was admitted to the hospital with well-marked symptoms of bronchopneumonia. Her temperature was 103°, pulse 120, and respirations 30. The left knee was red and swollen. The urine contained some albumin and a few granular casts. The Widal reaction was negative, and there was a leucocytosis of 11,600. On December 17 a small abscess, which had formed over the left patella, was opened. Examination of the sputum at this time showed pneumococci and streptococci. On December 23 the temperature began to decline, and the patient's general condition seemed to improve. On December 26 the temperature again rose to 104°, and for the next five days fluctuated between 100° and 104°, with a pulse of from 120 to 130 and respirations from 34 to 40. On January 2 the temperature reached 105.2°, the pulse 150, and the respirations 48. On the following morning the temperature fell to 99°. On the afternoon of January 3 there was a distinct chill, and since then there has been an irregular fever of a hectic type. On January 6 streptococci in pure culture were found in the blood. The highest leucocyte count observed in this case was 22,000, and occurred on January 10; the average had been 17,000, and at present the leucocytosis was 16,600. The patient had been growing steadily worse, and accordingly, on January 16, a formalin injection was tried at the suggestion of Dr. Barrows. Only about 250 c.c. were injected into the vein at this time. The temperature rose about one degree, or to 105°, after the injection. On the following day the respirations and pulse were better, but the average temperature range was only one degree lower than before. On January 18 the patient became distinctly worse, the temperature being 103°, the pulse 148, and the respirations 144. She was given an intravenous injection of 750 c.c. of a 1-to-5,000 solution of formalin. One hour later the temperature reached 106°, although before the injection it was 102°, with a rapid pulse and 60 respirations per minute. It should be noted that such a rise of temperature was almost the rule after an intravenous injection of saline solution. Examination of the urine of this patient failed to show any hæmoglobin in that fluid. Six hours after the formalin injection the temperature was 101.5°, the pulse was 150, and the respirations were 48. To-day her temperature had ranged between 103 and 104°, the respirations between 48 and 54 and the pulse between 140 and 180, and the patient's condition was so bad that a fatal issue was confidently predicted. Apparently in this case the injection of the formalin solution had exerted no material influence, either for good or for evil.

Dr. William R. Pryor said that he had always believed streptococcus infection to be merely wound infection. Streptococcus puerperal fever was an infectious process, entering the body through the uterus, owing to some injury. Only in 33 per cent. of fatal cases of this kind were streptococci found in the blood. They would occasionally disappear without treatment, and at times reappear. This condition was found in tonsillitis, in rheumatism, in bronchopneumonia, and in a great many other conditions. To determine whether or not a wound was infected by a certain noxious germ it should be examined for that purpose. So far as the uterus was concerned, there had been certain definite lines laid down, and these had been accepted by those doing most of the work in this field. The discharges should be collected according to a special technique, and if streptococci were not present the case should not be set down as one of streptococcus infection. Nothing had been stated in the paper to show that these cases were examples of streptococcus infection arising from the uterus; on the contrary, the symptoms presented were those of putrid infection.

Germicidal Injections an Old Treatment.—The method of injecting material into the blood had originated in the City Hospital, as long ago as 1896. The substance experimented with was iodoform, and it had been found that when this was brought in contact with the serous surfaces it was broken up and iodine liberated. Since that time he had treated twenty-seven cases by this method of inoculating the blood with iodine. The method had also been successfully tried by quite a number of others; hence, there seemed to be no good reason for relinquishing this treatment for even this brilliant departure inaugurated by Dr. Barrows.

Dr. J. Whitridge Williams of the Johns Hopkins Hospital, Baltimore, was invited to continue the discussion. He said that while he had been greatly interested in the report made by Dr. Barrows, he was compelled to view the subject with great reserve, because remarkable and surprising variations occurred in cases of streptococcus infection, irrespective of treatment. He had studied this subject for many years, and had found that many cases which were apparently hopeless had recovered without any treatment. He had known these cases to remain apparently in the last stages of the disease for a week or more, and then suddenly, without apparent reason, recovery would ensue. Mention was made of a case in which, after curetting the uterus, he introduced his finger, and, finding the cavity empty, had given an intrauterine douche of two liters of sterile salt solution. This was followed by a fall of temperature from 107° to 95° F. Subsequently, numerous streptococci were found in the blood. If this case had been treated by some medicated solution, instead of by sterile salt solution, this sudden change for the better would almost surely have been ascribed to that special treatment. Some years ago he had been associated with Dr. Pryor on a committee appointed to investigate the antistreptococcus-serum treatment. They had found that observers who reported favorably on the use of antistreptococcus serum based their opinion on not more than two or three cases, whereas those who formed an opinion only after having observed a large series of cases, invariably came to the conclusion that the antistreptococcus serum was of little or no use. Since the publication of Dr. McGuire's paper, to which reference had already been made, this author had made two other contributions to this subject. In one of these, presented to the British Congress on Tuberculosis, held in London in July, 1901, 100 cases of pulmonary tuberculosis, which had been treated by formalin injections, were reported. The treatment was published far and wide, and extravagantly lauded, but eighteen months later Dr. McGuire felt called upon to issue a note of warning, in which he stated that the results of this treatment were not nearly so brilliant as had been proclaimed in the press. Last year two other physicians had published a report of experiments made by them upon animals. These seemed to indicate that the formalin, instead of curing the disease, rather tended to accelerate its progress. It was also found that the bactericidal power of the formalin, when introduced into the peritoneal cavity was not at all marked. Various other methods of attacking bacteria in the blood had been tried, among others the injection of the silver salts recommended by Credé. The results from the latter method had not been brilliant, although in one or two instances coming under his own observation the injection of a small quantity of a 1-to-5,000 aqueous solution of silver nitrate had apparently yielded happy results. It was believed that the good effect of this method was dependent upon leucocytosis, but, unfortunately, in his own cases no leucocytosis had been observed. He believed that the method of attacking the bacilli in the blood was radically wrong, and he would not believe that Dr. Barrows had proved his contention until a large number of cases had been successfully treated by the method.

Danger of Curettage in Streptococcus Infection.—With regard to the use of the curette in streptococcus puerperal

infection, he would say that this practice seemed to him a very dangerous one; in his opinion, it killed more women than it saved. In a large number of cases the disease process was beyond the curette by the time the first symptoms appeared, while in the milder cases a protective wall of leucocytes was formed, and the destruction of this natural barrier manifestly would only invite further infection. He made it a rule never to use the curette when streptococci were found in the uterine cavity; he was even opposed, in such cases, to the use of the intrauterine douche, for the less disturbance and the less traumatism the better for the patient.

Dr. William M. Polk said that no report was considered complete nowadays that did not contain a statement as to the presence or absence of the streptococcus in the discharges, yet he imagined that most of those having much clinical experience in this class of cases were in a position to say that when a patient presented the appearance of Dr. Barrows' patient, and the discharges were those found in that case, numerous streptococci would be found in the discharges. The members of this association apparently did not recall an analogous discussion which took place about twenty-five years ago, when Déclat appeared and proclaimed the benefits to be derived from the introduction of carbolic acid—phenic acid, as he termed it—by hypodermic injection. At that time a number of cases were presented, which seemingly bore out the results which Dr. Pryor had spoken of as obtained from the use of iodine; but in those cases, as in others of a similar kind the results were finally proved to be against, rather than in favor of the method. To-day we were brought face to face with the proposition which presented itself to Dr. Barrows, viz., that we had no well-defined method of treating these cases when the usually accepted ones had failed. Dr. Barrows was, undoubtedly, thoroughly familiar with the great advantages to be derived from the injection of normal saline solution, but in the desperate case before him he had felt constrained to do something more—to try and see if some good might not result from the injection into the circulation of an antiseptic or a germicide. The advantage of the new treatment over mere saline infusion seemed to be the maintenance of a low temperature. Of course, one case would not prove the efficacy or the worthlessness of a method.

Dr. Barrows closed the discussion. He emphasized the fact that in the case reported by him all the recognized surgical procedures had been used, and yet the streptococci were in the blood in large quantities, and the woman appeared to be *in extremis*. Within a very short time, as shown by the cultures, the streptococci disappeared from the blood, and the woman's condition rapidly improved. The case was not reported as one of puerperal septicæmia, but as one of acute streptococcus infection.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 17, 1903:

	Cases.	Deaths.
Measles	165	10
Diphtheria and croup	395	47
Scarlet fever	153	16
Smallpox	2	1
Varicella	124	..
Tuberculosis	248	183
Typhoid fever	64	10
Cerebrospinal meningitis	..	..

His Currants a Specific.—The Greek was just an ordinary push-cart man, except in one thing—he believed in advertising. He stood beside his cartload of currants on a wind-swept corner of City Hall Park. He maintained a stoical silence, depending, perhaps, on this sign to sell his goods: "Currants as against the Chill, Cold, and Catarrh as More Eat, More Want, Very Nice of Easy Digestion." A sign like that could not escape the attention of watchful New-Yorkers, and many bought. When he was not dealing out the dried fruit he was busy keeping his bare hands warm. They were dirty hands, but one did not notice it, unless he happened to be arranging his stock; as he did every little while by brushing his hands, dirt and all, over the currants.—*New York Tribune.*

Habitual Death of Fœtus.—Where the cause is not specific, potassium chlorate should be given continuously from the end of the third month, in ten-grain doses, after meals. The drug has a beneficial effect upon the endometrium. Jardine (*British Medical Journal*) reports five successful cases.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending January 17, 1903:

SMALLPOX—UNITED STATES.

THE OPEN-AIR TREATMENT OF SYPHILIS.

By EDWARD H. DOUTY, M.A., M.D. Cambridge, M.D. Lausanne, Davos-Platz, Switzerland.

Formerly Lecturer in Cambridge University, England.

I do not remember having ever seen the open-air treatment of syphilis advocated in any of the many journals of Great Britain or of other countries; and yet there is, I venture to think, no argument brought forward in favor of the open-air treatment of tuberculosis that is not equally to the point with regard to early syphilis. I suppose that there are a great many medical men, and others, who, because they have not thought about it, have an idea that the open air has some direct influence on the lung tissue in consumptives, just as, I find, there are very many who believe that the cold of these Alpine heights has direct affect on the lung tissue, and on the bacilli in it.

But a little thought will show them that it is not the influence of open air on the lungs which brings about the cure of pulmonary tuberculosis, but that it is the influence of the pure air and sunlight on the blood, and through it on all the other tissues of the body, and chiefly the nervous tissues, that the good results are obtained. Fresh air heightens metabolism in every way, and raises all the tissues to their highest point of resistance, so that they do not succumb to the persistent attacks of the poisons constantly carried hither and thither by the circulating blood.

The nervous system responds the most readily to the purer and richer pabulum brought to its inmost recesses by the blood, and as its cells are better nourished, so its trophic influence is maintained, and the metabolism and growth of all tissues, including the all-important hæmatopoietic, are ensured and maintained at their highest, and they are thus enabled either actively to beat off, or passively to refuse to succumb to, the specific poisons of any disease. Open-air life improves the appetite, and, again, the additional food ingested improves the blood-pabulum with the results referred to above. Carefully graduated exercise again increases the appetite and stimulates the emunctories, and helps the elimination of their excreta. Rest, much rest, carefully prescribed at suitable times and under correct conditions, again helps much. And if this can all be done away from home surroundings and worries, in a high, dry, bracing climate, with the purest possible air, with pleasant companions and environment, the greater will be the efficacy and permanency of the whole treatment.

Open air, then rest, high feeding, graduated exercise, and, if possible, a bright, dry, bracing climate, are our means for enabling an individual to escape the eventual horrors of consumption. But all and each of these are, in my opinion, as important in enabling the individual to escape the eventual horrors of syphilis (with the help of small doses of mercury maintained for many years.)

The parallel is strict. The poison, whether it be a bacillus or a ferment, an enzyme, a toxic-albumose, or we know not what, is there in the individual. It is somewhere in the system. It may be weak, it may be strong. Or the resisting power of the individual tissues may be weak or may be strong. Or the idiosyncrasy of the individual may be such as to render him well nigh immune; or, particularly susceptible. The poison may be causing actual physical signs and symptoms, or it may be apparently latent, but powerful for evil, and perhaps gaining strength wherewith to strike with thug-like precision and force when long forgotten and least expected, and when inadvertently the unwary victim has laid himself open to attack by being run down through worry, overwork, or neglected ill-health. It matters not whether the poison be the syphilitic or tuberculous—it may suddenly seize upon the lungs, larynx, nervous system, or connective tissues.

Surely if the open-air treatment is called for at the beginning for the one, it is equally so for the other, to avert the staggering consequences of the original infection. And yet I have never seen it advocated equally for both.

In syphilis mercury undoubtedly does good. Probably, until the last thirty years, it has, I think, done more harm than good. It is not an antidote to the syphilitic poison, any more than iodide of potassium is. It probably helps the tissues of the syphilitic, much as I find that arsenic sometimes seems to help the tissues of the tuberculous. I do not feel that it is a specific, and Diday, whose work on the subject seems to me to carry much weight and conviction, certainly seems to teach the same.

During ten years in a busy practice in the University town of Cambridge I saw many young men with early syphilis, and I often kept in touch with them for many years after they had gone down from the university. And one thing impressed me much; that whereas a poor, underfed scholar, if infected, was hit painfully hard, the well-to-do, hunting, or athletic undergraduate generally suffered lightly. The latter led an open-air life, he ate meat three times a day, his tissues were well nourished, and, therefore, at a high resistance pitch. But the scholar, often poor, trying, because of the *res angustæ domi*, to live on his scholarship, who generally had porridge for breakfast, bread and jam for lunch, and a poor dinner in hall, sometimes at a dreadful time of day, badly served and hastily eaten or left, he, I noticed, often suffered badly. And this, too, in spite of the fact that the sporting undergraduate was often very casual about taking his mercury. He very often, however, got off cheap, had but slight secondaries, and heard no more of his trouble. For, later on, he continued to live a well-fed, open-air life, often as a country gentleman or in some other easy-going position in life.

I remember, some ten years ago, remarking on my observations to Sir George Humphry, before the "open-air treatment" had come to stay, and he said that throughout the enormous experience of fifty years' practice in Cambridge he had always noticed the same thing—that the well-fed sportsman,

in spite of his being casual about his mercury, did not hear much of his trouble in the afterward, and I remember his adding, "Ah! I used in the old days to salivate them to pints a day!—but they wouldn't stand it, and they seemed to do very well without. He remarked, too, how heavily the poor student often suffered, although he was conscientious and regular in taking his mercury. Perhaps he was given too much and became miserably ill with his throat, and rash, and aches, and fever, and early skin affections, and horrible melancholia. I can think of four such now. One has spastic paraplegia and is living; another is dead of general paralysis of the insane; the third has locomotor ataxia, and the fourth is insane, also with ataxia, and I hope by this time dead. Three out of the four became fellows of their college.

If the athlete chronically poisons himself with alcohol, and leads a dissolute life (I mean, when syphilitic), he goes to grief—but later on. I have seen six such cases within the last three years—magnificently developed men, and with grand records as athletes. One died of phthisis, the second of appendicitis (tuberculous), the third of cerebral hemorrhage. The fourth of arterio-capillary sclerosis and kidneys, the fifth is just alive, and has phthisis, the sixth died of phthisis and chronic Bright's disease. They had all drunk hard, and had lead unhealthy, town-loafing and dissolute lives. All the five died here in Davos at or near forty years of age.

During five years' observation of patients in these high Alpine altitudes, I have come to the conclusion that 30 per cent. of the men patients here who have phthisis are syphilitics—and, perhaps, more. They are, as a rule, men of the upper middle class, who have led hard-working business lives. They are a type of case that clinically one can recognize, and their want of healthy carmine color and their thin hair or baldness leads one to suspect them. It is wonderful how this class of case improves here, if not too far gone. Mercury gently given certainly does them good. I notice that they are specially liable to ischio-rectal abscess and fistula in ano, and to ear trouble and deafness, more so than other phthisical patients. They are generally between thirty and forty years of age, and though they yield quickly to treatment and improve much, they seldom are quite cured. If only they had undergone a long open-air cure directly the character of their syphilitic infection was recognized, I believe they would not have had to come here for the open-air cure of their phthisis.

I have asked many directors and assistants of sanatoria and hospitals on the continent, and they have put the proportion of the syphilitics among the phthisical men as 30 and 40 per cent., and twice lately I have been told 50 per cent.

Dr. Klause, assistant to Professor Koch, and Chief of the phthisical wards at the Charité at Berlin, told me last month that fully 50 per cent. of the men were syphilitic. He also told me that when in charge of the venereal diseases department he noticed that more than 50 per cent. of the patients showed physical signs of lung disease.

The German mutual benefit and insurance societies find it pays to establish open-air sanatoria for their phthisical members. I think they would do well to do the same for their early syphilitic cases.

But the trouble is that the man who finds he has contracted syphilis is only too anxious to conceal the fact that there is anything the matter with him. He is depressed, he loses his spirits, and mopes indoors, loses his appetite, pins his faith on the mercury, takes too much of it, and then when the ill-feeling of the secondaries comes he goes from bad to worse, and is for months in the worst possible condition for resisting the invading poison at the most critical time. He is sent, it may be, to Aix-la-Chapelle or Wiesbaden, where he leads an unhealthy hotel life. Far better if he were sent at once to an open-air sanatorium, to lead the same life as is laid down for a patient with slight tuberculosis. Or, better still, if he were sent to a high, dry, bracing climate, such as the African Weld or the high Alpine plains of Central Europe, where he can amuse himself gently out of doors for six months or a year, under supervision, and then take to sport to keep him happy and healthy, among numbers of other people all busy in the pursuit of health or pleasure. For I notice that early syphilitics do extraordinarily well in these Alpine heights. Blood changes here are rapid; metabolism throughout is heightened, and the patients rapidly regain health, their throat and rash disappear very quickly, and their pains and fever rapidly go, when they have acquired the appetite which the dry, cold air seems to force on them. And I find that very little mercury goes a long way.

He should devote certainly one year to an open-air life, and, if he can afford it, two years. I believe that then we should not have the 30 per cent. of men syphilitic phthisical patients, and the million of lives per annum which tuberculosis at present costs Europe would also be very much reduced. Of course, with the laboring classes, it is probably useless to dream of their getting a year or two. But they might get, as they do for tuberculosis, three or four months, though very few of them would take it if they could get it, I feel sure. But how about compulsion? We use compulsion in case of smallpox—why not for great pox?

This leads me to the question whether our national and international associations and leagues against tuberculosis should not, in considering the prevention of tuberculosis, attack this great source of it, viz., syphilis. And should they not advocate the open-air treatment of syphilis? And should they not agitate ceaselessly for rational legislation on the point? I see great authorities speaking sanguinely of "stamping out this scourge (tuberculosis) of the human race." I believe there is no hope of stamping out "this scourge" without also taking means to stamp out the other even greater scourge—syphilis. We should consider the soil, not the seed. The tubercle bacillus will always be among the flora of damp, dark countries, and while syphilis is plentiful, ever providing a suitable soil, tuberculosis also will flourish.

I do not believe that our National Association against Tuberculosis will ever start a crusade against syphilis unless the King, or some other strong man, or some independent members of committee, take a strong line on the subject.

Many I know will say that my estimate of syphilitics among phthisical men is too high. I feel confident that when they have made as full inquiries and observations as I have made, they will not be of that opinion. I refrain from offering the usual meretricious attempts at proof by plastic statistics. The last five years have sickened me with their rich supply of lying half-truths.

I hope that the open-air treatment for early syphilis may become more usual, and I hope that the National Association against Tuberculosis may advocate it. It need not be known whether the patient has tuberculosis or early syphilis, let the treatment be the same. By helping him to live down his syphilitic poison, we can prevent the chronic inflammatory processes which undoubtedly

afterward provide the soil for the tubercle bacillus. Surely this is not only a wise, but a very necessary policy. I firmly believe that half a million deaths a year in Europe would be prevented by this policy.

But I fear that by taking a strong line and striking at the root of much of the evil, the National Association would run the risk of alienating much valuable sympathy, for there are many worthy people whose firm convictions lead them to entertain the *vox populi, vox Dei* theory. I do not remember having seen the open-air treatment of syphilis advocated in our journals. And yet it has long been clear to me that it is absolutely as loudly called for as the open-air treatment of tuberculosis.

When a patient who comes to us is proved to have early tuberculosis we say to him, "This is serious. If you can afford it, you must give up your work, and go away for six months and be over fed and live in the open air in the best possible climate. After that, if you can afford it, you had better live for another year or two in the open air." I contend that we should do well if we did exactly the same with an early case of syphilis.

A CASE OF DISEASE OF THE ACOUSTIC NERVES, CAUSING PROFOUND DEAFNESS, ACCOMPANIED AT A LATER STAGE BY PLEURITIC EFFUSION AND FIBROID PHTHISIS—RECOVERY.

By D. B. St. JOHN ROOSA M.D., LL.D.,
NEW YORK.

In September, 1888, at the meeting of the Fourth International Congress of Otology, held in Brussels, I read the account of a case illustrating the harmful effects upon the ears of the internal administration of the sulphate of quinine.* The case was then, as I supposed, at a standstill, the patient having recovered the hearing in one ear, while the other remained deaf. But in the years since then, so many important changes have occurred, with a final recovery, which has now endured for more than two years, that I republish the first part of the case, with the subsequent history:

On the 27th of February, 1888, I was called to see an officer of the United States Navy, forty-nine years of age, who, in the discharge of his duty, had received a severe wetting the night before, and suffered a chill. On returning home he took at least 20 grs. of the sulphate of quinine, with some whiskey. He perhaps took more than 20 grs., but, at any rate, he took this quantity. He felt himself much better in a short time; he went to bed and slept well, but on waking in the morning he found himself unable to hear conversation. I saw him in a few hours, and I found that he could not hear a watch, that should be heard at forty-eight inches from the ear, at all, and the voice at one foot, but with difficulty, and directly in the ear. My diagnosis was congestion of the acoustic nerve, caused by the wetting and the quinine. The first treatment was the administration of calomel, with blisters behind his ears. There were no symptoms in either drumhead, no vascularity. He could not hear the *C* tuning fork at all through the bone. Besides the deafness there was considerable vertigo, but no difficulty in locomotion. Two days after, the hearing was no better, but the vertigo was diminished. Bromide of sodium was then administered. On the 7th of March the patient was without vertigo and headache, but the hearing power remained the same. Mercury and iodide of potassium were then used, with injections of a two-per-cent. solution of muriate of pilocarpine, 4 minims. Nausea and ptyalism were caused, but there was no change in the hearing. I then turned about in my diagnosis, for whatever may have happened immediately after the quinine and the chill, since all the antiphlogistic remedies had failed, I was led to the conclusion that there was anæmia of the acoustic nerves, instead of congestion, and I commenced the use of sulphate of strychnine, hypodermically. In a day or two the patient began to improve, and on March 15 he heard conversation with some difficulty, on the left side. The aërial conduction was very feeble, there was no bone conduction whatever, no tinnitus aurium. He was taking three milk punches a day of whiskey and a 30th of a grain of sulphate of strychnine twice a day, with red wine, Bordeaux, at dinner.

On March 21, strychnine still being taken, as well as the alcohol, the patient heard more easily in the left ear. There was no bone conduction on either side. The vowels were heard through a tube or directly in the ear, with some difficulty, on the right side. He continued to improve, the treatment by strychnine and alcohol being continued, and on the 4th of June, a little over three months since the trouble began, he heard conversation in an ordinary tone, by the left ear. The use of the hearing trumpet in the right ear, where he still could hear the vowels, caused pain. The patient remained in this condition, which was considered by me as probably permanent, until the winter of 1890–1891, when he was attacked by pleurisy on the left side. His convalescence was slow, and in May of 1891 he was seen by an eminent physician, who advised him to seek a change of climate. He spent the winter of 1891–1892 in Colorado Springs, and was very much improved, except that he continued to have considerable cough. He remained in Colorado two-thirds of the year, until the spring of 1895. In the winter of 1893–1894 his hearing became worse in his good ear, and it was so much affected that he could hear ordinary conversation with great difficulty. He, however, recovered under the use of strychnine. It should be said that the physician who saw him after his convalescence from pleurisy pronounced his case one of pulmonary phthisis. He had pulmonary hemorrhages at certain times, and tubercle-bacilli were found in the sputum by an expert microscopist. The case was finally grouped as one of fibroid phthisis. Between 1888 and 1900 there were three attacks of impairment of hearing in the better ear, but from each of them he recovered, until 1898, when he returned to New York from Colorado, in a most deplorable condition. Although a good-sized man, some five feet ten inches in height, he only weighed 126 pounds, he had a most distracting cough and was profoundly deaf. He could hear the voice in his better ear by the aid of the hearing tube with the greatest difficulty, and although able to go about, he avoided society, and communicated somewhat by writing. He then came under my care again, and I placed him upon increasing doses of sulphate of strychnine, given internally, three times a day. I also gave him Russell's emulsion, and in three months his hearing was restored not only in one, but in both ears. His cough was nearly gone, and he had gained some twenty pounds in flesh.

It is now more than two years' time since this last recovery, and his hearing remains normal in both ears, and although he still has a cough, with considerable expectorations, he looks and acts like a man in good health.

A recent examination by an expert shows that

*Transactions of the Fourth International Congress of Otology, 1889.

his cough depends upon bronchitis, but he has no signs of tuberculosis.

Remarks.—The interesting points in this case are twofold: First, the recovery from profound deafness after a lapse of so many years—from 1888 until 1898 he had not been able to hear from the left ear. He had had three attacks of impairment of hearing, tinnitus of the ear, after the original seizure. But in 1898 both ears became and remain normal.

Second, the patient has a good degree of general health and his pulmonary symptoms have improved very much, although spending most of the past four years in the city of New York. For some unknown reason his pulmonary symptoms had, as stated before, become again quite serious when he returned from Colorado the last time. The treatment I adopted was the administration of Russell's emulsion and strychnine, with the regimen recommended by Dr. John F. Russell. He has spent July, August, and September each year in the State of Maine, a few miles from the coast, in a place where the soil is dry and sandy. The patient was in a condition to carry out all proper hygienic measures as he was from the first. He still lives in New York in the winter, and during the summer in Maine, and enjoys as good health as most people of his age, having now reached sixty-six years.

In the inception of the attack I supposed the disease to be of a congestive variety, but all treatment directed to the lessening of inflammation—mercury, iodide of potassium, pilocarpine, leeching, and so forth—was not only of no avail, but the patient grew worse under it. As soon, however, as I turned to the stimulating treatment—strychnine and alcohol—he immediately began to improve.

The final recovery was due also to the same character of treatment, except that on account of a marked gouty diathesis, alcohol was omitted. It is impossible to say what the lesion in the acoustic nerve was. It may have been in the vestibule, and not in the cochlea. It was hardly in the semicircular canals, because his equilibrium was disturbed very little, except in the very beginning—in 1888.

It has been to me a very refreshing oasis in the desert of chronic aural disease, especially one involving the labyrinth, to note a recovery such as this.

The theory that the disease was for a few days of a congestive variety and then became an anæmia is quite in accordance with the results of my experiments with quinine upon healthy ears,* and with the ocular conditions after excessive or toxic doses of quinine, as shown in the case reported by me,† and similar ones afterward reported by other writers.

20 East Thirtieth Street.

Late Disease of the Brain after Injuries.—Stadelmann says that the diagnosis in these cases is most difficult when the so-called late bleedings come on weeks or months after the injury. He would rather call such cases late apoplexies in distinction to traumatic secondary hemorrhage. In order to bring the cerebral changes into connection with the disease, the following conditions must be fulfilled: (1) The patient must have been healthy and sound before the receipt of the injury, and must not be of great age. (2) The injury must have been considerable. (3) The symptoms must have developed before our eyes. According to some authors, the diseased vessels must be opposite to the injury. The author relates cases in which the symptoms developed in two and a half years, four weeks, and seven weeks respectively after the injury. —*Medical Press and Circular.*

THE PRINCIPLES OF PROTECTION AGAINST RÖNTGEN-LIGHT DERMATITIS.

By CARL BECK M.D.,
NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING SURGEON TO THE ST. MARK'S HOSPITAL AND THE GERMAN POLIKLINIK.

As long as the specific effect of the Röntgen rays upon the sensitized plate and upon the organism are alike unknown, it is impossible to make definite rules for protection against their possible injuriousness. But experience has taught us that in all cases of Röntgen-light dermatitis, other circumstances being equal, long exposures had taken place; and it is, therefore, obvious that short exposures are the best safeguard against injury. But then the question is, Shall we reach the desired result, whether for diagnosis or therapy, by a short exposure? If not, what else must be used for proper protection?

In order to appreciate this important point thoroughly, we must also consider some contributing factors, viz., the construction of the tube, the penetration power of its light, the distance from the irradiated body, the position of the object, the number of interruptions, and the size of the secondary.

Whether an accumulator, a static machine, or a coil be used, seems to me to be irrelevant. But, as mentioned in my previous publications on this subject, I believe that we have to reckon with Röntgen-light idiosyncrasy, existing in some individuals just as much as we have to with an iodoform susceptibility. My statistics at the German Poliklinik of New York, which are based upon twenty years of continuous observation, show that about every fiftieth individual becomes affected with dermatitis when treated with iodoform. Since such idiosyncrasy cannot be diagnosticated before the dermatitis makes its appearance, we shall never be able to prevent it. But what we can do is to recognize it in its early stage, and if this be done, further spreading can be arrested by simply discarding its further use.

There are, however, two points of difference between the iodoform and the Röntgen-light idiosyncrasy. In the first place, a non-susceptible patient will not show any signs of iodoform dermatitis, no matter how long he may iodoformize himself, while there is no individual who would not be burned by the Röntgen light if its influence is kept up long enough. And, secondly, the Röntgen-light dermatitis will not stop as soon as further irradiation is discontinued. The peculiar features of the Röntgen rays not to show the injurious effects as a rule before the tenth, sometimes not before the twentieth day after the first exposure, stands in the way of an early and rational prophylactic therapy. The only method by which we may so far determine whether an idiosyncrasy exists or not, is by tentative exposures. So it may sometimes be a chain of little causes, long exposure, short distance, powerful apparatus, condition of patient, and weather, which in their entirety may be the stimulus for the reaction. Besides this idiosyncrasy, which is born with the individual, and is to be regarded an imponderable, a temporary susceptibility exists, which may be attributed to temporary bodily conditions, to pathological changes, or to climatic influence. I have called attention repeatedly to my observation that when suffering from slight Röntgen-light dermatitis myself, I could note a marked increase of the symptoms during sultry weather. The patients treated at such days had a similar experience.

I do not believe, however, that the question of idiosyncrasy requires much consideration, as far as

FIG. I.—Epithelioma of eyelid of four years standing

FIG. II.—Epithelioma of eyelid cicatrized after twenty-four exposures, the epithelioma of the lower lip showing its first signs

FIG. III.—Epithelioma of lower lip.

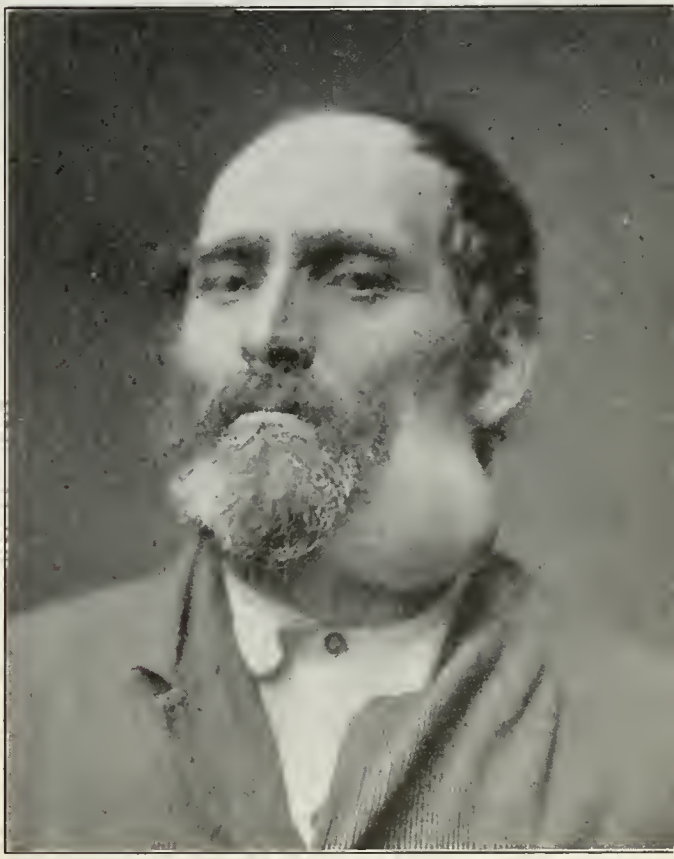

FIG. IV.—Carcinomatous tumor of inferior maxilla and submaxillary tissues, fifteen months after the cure of the epithelioma of the lower lip. (Compare Fig. III.)

exposures for diagnostic purposes are concerned, since, with our present methods, the length of time needed is much shorter. Even if repeated exposures have to be taken, I have not, thus far, seen a Röntgen-light dermatitis before the fifth repetition, the intervals having been from two to three days. And these cases were slight—the first or second degree. Still, as already said, with our present apparatus, a certain length of exposure invariably causes burning, whether the individual be susceptible or not. If long exposures are responsible in nearly all cases of Röntgen-light dermatitis, we shall naturally try to shorten them. This we can do only to a certain extent, if we are seeking full and distinct diagnostic information. Unfortunately, the best skiagraphs are obtained by long exposures, made with tubes of low vacuum. This, in addition, requires the use of a strong current. So, in order to get out the structural details, three irritating factors unite their influence, the long exposure, the soft tube, and the intense current. A tube with a high vacuum requires only a short exposure, but the details of the skiagraph are by no means brought out as well. So, theoretically, if the question of dermatitis did not exist, we would, as a rule, combine very low vacua, very long exposures, and currents of high intensity.

Fortunately, the longest exposure (the pelvis) does not now, with the aid of the Wehnelt interrupter, require more than ten minutes' exposure, and this will be tolerated even by a susceptible individual. So, practically, we do not need to fear much in our diagnostic efforts, and if we could make the rays still more powerful, in order to get more differentiation, we would not hesitate to do it.

But when repeated exposures of ten minutes time are necessary, the question of idiosyncrasy, as well as of ordinary cumulative irritation, should be considered, and therefore the intervals between the exposure should be made long—a week on an average.

The chromoradiometer of Holzknecht represents an effort to solve the uncertain question of proper dosage. It consists of an arrangement of various salts, which possess the property of being more or less colorized by the influence of the rays. After they are deeply colorized by the rays, they are made up in a scale, which also contains the same salts, not yet influenced by the rays. If the fresh salt, placed at the object to be irradiated, shows the same degree of colorization which its colorized companion has, sufficient influence is exerted, and further irradiation would better be stopped. Ingenious as the apparatus is, which is especially recommended in the treatment of lupus, it will, in its present shape, not take the place of our simple means of control.

Protection in exposing for diagnostic purposes is a chimera. If a so-called protecting shield really protects, then it is an obstruction to the rays, and consequently the details of the skiagraph are lost. In marked injuries the details may be recognized; but they will not be distinct, and can be compared with the skiagraph taken through a plaster-of-Paris dressing, which is only of value in connection with a skiagraph taken before the dressing was applied.

If the rays are used for therapeutic purposes, the possibility of susceptibility deserves attention. It seems to me, however, that we should make clear to ourselves first what the object of our therapeutic measures is. Little stress is laid upon this point in the many valuable publications on this important subject. It is not customary to shoot at sparrows with cannon balls. Why, if we treat a hairy surface on the face of a fair lady, for instance, resort to means as powerful as those we employ in carcinoma? In other words, when treatment for non-malignant disease is intended, careful tentative exposures should precede it. If, then, erythema should appear after one short exposure, thus proving the presence of idiosyncrasy, further treatment must be taken up only under extraordinary circumstances, and after the patient has been fully informed of the risks. For such purposes I have advised a first exposure of five minutes. A soft tube should be selected, and the Röntgen light must just be strong enough to show the carpus of the operator black, without structural details and contrasts to the soft tissues. After a week the same procedure, now lasting ten minutes, is to be repeated. If, after a third exposure, and two weeks after the first, no reaction has shown up, the patient is, apparently, not susceptible. Then he may be irradiated every second or third day, and at last daily, until reaction manifests itself. Each exposure may last from ten to fifteen minutes.

During the tentative exposures, the distance of the tubal wall from the skin should be four inches. The vicinity of the irradiated area must be protected. This is done by a thick shield of lead, which, if moulded properly, attaches itself to the area selected; if not, it must be fastened to it by a bandage. If the face is concerned, a sheet of lead, into which a hole is cut to correspond with the area to be irradiated, may be bent over it. These principles apply to all cases of benign integumental disease.

In treating malignant diseases, we should be governed by entirely different principles. I have emphasized repeatedly that nothing appears more absurd than protecting the area which demand the influence of a sort of a destroying agent. Since Volkmann found, on microscopical examination, that even in small and superficially located carcinomatous growths of the mammary gland, the fascia was generally involved, he was naturally led to the conclusion that removal of the tumor alone was an insufficient procedure. The correctness of his investigations was corroborated by Heidenhain, who found carcinomatous cells in the superficial layer of the pectoralis major muscle, even when the breast was only superficially involved. From these observations we learned that the removal of the fascia would not suffice, but that, at least, the superficial layer of the pectoralis major muscle should be dissected away in all cases, even when the carcinomatous nodule was but of small size.

The observation of the following case, represented by Figs. 1 and 2, illustrates these views strikingly. The patient, who is ninety-one years of age, suffered from epithelioma of the eyelid for four years. He was treated chemically, especially with caustics. No attempt of excision was ever made. The patient was greatly disturbed by the excruciating pain in and around the deep ulcer. (Fig. 1.) All efforts to give relief proved to be failures until an attempt was made with the Röntgen rays. After the first exposure, which lasted five minutes, the pain was considerably lessened, and after the second exposure, two days thereafter, it disappeared entirely. No protection was given, except that the patient closed his eyes during the séance. Sometimes the distance of the tubal wall from the skin was not more than half an inch.

Although, after the nineteenth exposure, slight erythema developed, the séances were not stopped until, after the twenty-second, painful dermatitis showed over the face. Further irradiation was stopped then for two weeks, when all signs had disappeared. The remainder of the ulcer was dusted with xeroform, which was also used in the intervals. After three more exposures the epithelioma had

FIG. V.—Röntgen hand.

FIG. VI.—After operation for the ninth recurrence. (Compare Fig. VII.)

FIG. VII.—After first amputation, February, 1894.

FIG. VIII.—Röntgen-light burn of third degree in sarcoma of superior maxilla, frontal bone and orbit.

fully cicatrized. (Fig. 2.) At the same time an epithelioma showed its first signs at the lower lip. It is treated with Röntgen light at present. The eye is in no way affected.

It must be assumed that while the macroscopical evidence of carcinoma was concentrated upon the eyelid, the cells must have been spread around the lymph vessels of the whole face, thus, finally, establishing a focus in the lower lip. The case, illustrated by Figs. 3 and 4, is analogous. It concerns a man of fifty years, whose epithelioma of the lower lip (Fig. 3) was cured fifteen months ago, and which, up to the present time, has not shown any signs of recurrence. Three months thereafter a small nodule appeared in the left submaxillary region, the removal of which was refused by the obstinate patient. No treatment of any kind was submitted to until a short time ago the patient presented himself with the large tumor illustrated by Fig. 4, which extended from the geniohyoglossus muscle up to the parotid gland. As could be ascertained by skiagraphy, as well as by subsequent resection, the bone showed slight erosion at its lower anterior border. The microscopical examination, made by Dr. R. H. Buxton, revealed the presence of a large number of cell nests in the epithelioma. An extensive operation, consisting in the exsection of the left half of the mandible and removal of the parotid gland, the temporal, the masseter, and the sternocleidomastoid muscles was done. Recovery was uninterrupted.

It did not take long for the conclusions of Volkmann and Heidenhain to bear rich fruits. The surgeons who followed Volkmann's example were soon able to report cases which showed no signs of recurrence until after more than a year. Kuester, Senn, Halsted, Weir, Meyer, and myself (Medical Society of the County of New York, November, 1892) advised still more radical steps, with more or less modification of the original method.

The motto "Better too much, than too little" must be adhered to in malignant disease, as emphasized in my previous publications. It is better, therefore, to suffer from slight functional disturbances after sacrificing the whole pectoralis major and minor muscles than to attain a good functional result followed by a speedy recurrence.

Now, if we are convinced of the fact, that even when there is only a small carcinomatous nodule in the mammary gland, the superficial layer of the pectoralis major muscle contains or may contain, carcinoma cells, why restrict ourselves then, if we attempt to treat a nodule of this kind by the Röntgen rays? Is it not exactly the contrary of what we desire to achieve, if we prevent the distant carcinoma cells from being reached by covering the vicinity with some impermeable metal? We want to reach *all* carcinoma cells, if we can, and the so-called shield does not shield the patient, but the carcinoma cells. Therefore, shields off in malignant disease! The contrary procedure would be just like ruling that, after a certain amount of blood had been lost, an operation must be stopped, even if its completion would save the life of the patient. If we have made up our mind to influence the carcinoma cells, we must employ sufficient energy to enforce this result.

This does not imply, however, that the other extreme should be striven at. We must follow our therapeutic strategy in a determined, but carefully observant manner. The practical *modus operandi* is, therefore, about the following:

The patient suffering from malignant disease is irradiated without first submitting to tentative exposures. The tube should be as near the tumorous area as possible, the distance of the tubal wall from the skin never exceeding two inches.

This is done for the purpose of influencing the growth itself as powerfully as possible. After there is a slight erythematous reaction, within the immediate vicinity of the growth, the distance is increased for the following séance. Thus the rays reach a larger surface. In mammary carcinoma, for instance, the area between the sternum and axilla must be fully exposed.

When this wider field becomes erythematous also, the irradiation must be stopped for a few days until it shows signs of disappearance. It is not advisable to wait until the last little sign of dermatitis has vanished, because much valuable time may be lost by waiting. Repeated attacks of dermatitis may thus be endured.

It seems to me that the further the carcinomatous infiltration has extended, the more resistance to dermatitis exists and, consequently, the less reaction takes place, the cell-metamorphosis lowering the irritability of the skin. This non-susceptibility, of course, varies with the different types of malignancy. It seems to be greatest in the fibrous variety of carcinoma.

If there be extensive ulceration, causing retention of pus, irradiation should not be continued until the area is exposed fully, and any necrotic tissue removed by the scalpel or sharp spoon. If this is omitted, the power of the rays is not only inhibited, but, at the same time, toxæmia from local decomposition is added to cachexia, a very dangerous association, indeed.

If the integument is concerned, soft tubes must be employed, but deeper infiltration requires tubes of medium hardness. It is obvious that for very deep-seated growths, hard tubes should be employed, in view of their greater penetration power. But I do not believe that the rays, in their present capacity, possess so much force in the deeper tissues of the body that a regressive metamorphosis can be expected. That even carcinoma of the stomach, liver, or uterus may be influenced, is not denied, but such influence is not intense enough to promise more than a slight amelioration. *Ne quid nimis!* Extravagant promises will discredit the new and delicate field of Röntgenotherapy.

I do not maintain that the production of dermatitis in the treatment of malignant disease is desirable or a *conditio sine quâ non*. But, with our present means, I regard powerful and long irradiation a necessity, and this, unfortunately, entails the provocation of the dermatitis.

My experience shows that whenever a dermatitis has appeared the size of the growth has diminished, œdema and pain has decreased, and the general condition of the patient has improved.

In spite of extensive dermatitis, which causes a most distressing burning and itching sensation, all the patients suffering from malignant disease were anxious to undergo irradiation again as soon as possible. If the *raison d'être* is thoroughly explained to the patients, they will certainly not make their physician responsible for excessive burns. A patient afflicted with carcinoma or sarcoma, especially if it is inoperable, has, indeed, nothing to lose, and can well afford the risk of being burned. Will he act like the boy who, for tearing out a lock of his scalp when he was drowning, threw rotten eggs at the man who pulled him out of the water? And, in any case, the physician is a soldier, and must do his duty, unconcerned whether he is applauded or insulted.

Of course, the purely cosmetic standpoint is entirely different. If dermatitis occurs in the face of a fair lady, who simply wanted to be treated for

hypertrichosis, the cure proves to be worse than the disease.

For lupus, epithelioma, and integumental sarcoma, a séance of ten minutes, repeated every second or third day, suffices on an average. Extensive and deeper-seated growths should be irradiated daily for the same length of time, and, if no intense reaction appears, for twenty minutes.

As soon as improvement is noted, the exposures should, for a while, be shorter and the intervals longer.

While the motto of the physician is *summa lex ægroti salus*, there is no reason why he should forget his own "ion" entirely. Fig. 5 shows the wrinkled, shrivelled, vulnerable, and partially cracked terra-cotta hand of a physician, who has done daily skiagraphic work since the early Röntgen era. It represents the dorsal surface, which he turns against the Röntgen tube to ascertain, by the study of the bones of his own hand, what degree of translucency exists. The tip of the fourth finger was the most exposed target, which finds its conspicuous expression in the black colorization of the nail and the onychia. Next to it the little finger suffered most, which is illustrated by the deep black of its nail. The nail of the middle finger is less blackened, and the index still less, while that of the thumb, which is held sidewardly, is fairly normal..

As long as one's own carpus must be the means of ascertaining the degree of the tubal vacuum, the operator cannot protect his hands sufficiently. because the protection would impair distinction. He can do a great deal, however, by preparing everything carefully before the tube is lighted, and by keeping out of the focus when it is not absolutely necessary. The same hand must not be used for autodiagnostic purposes all the time, but it is advisable to change hands methodically, using the right hand at one séance, and the left at another.

For therapeutic purposes the continuous control of the light is unnecessary, and there is no reason, therefore, why the operator should come in close contact with the rays. In regard to this chronic type of Röntgen-light dermatitis, I refer to my previous publications, in which the temporary alopecia, the atrophic thickening, and the pigmentation of the integument, was described. The chronic Röntgen-light dermatitis may, if abstention is not resorted to for a while, lead to progressive ulceration, which, by passing through the rete malpighi, may give rise to extensive destruction. Pigmentation is a most characteristic sign, and may, in fact, be regarded pathognomonic in contradistinction to other kinds of burns or dermatitis. The pathological and therapeutic aspects of the effects of the Röntgen rays, MEDICAL RECORD, January 18, 1902 (see Fig. 3).

Valuable information as to course and therapeutic influence can be gained from the observation of a patient of fifty-nine years, who began to suffer from carcinoma of the breast ten years ago, and who, after having been operated upon ten times, enjoys fairly good health at the present time. (See Fig. 6.) The result of my first operation, performed in February, 1894, was illustrated six years ago (*Clinical Recorder*, October, 1896). She had not asked medical advice until a year after the first signs had shown themselves. There was an extensive carcinomatous area then of the left breast, the axillary glands also being involved. The extensive destruction and the pain appealed to her at last. It is self-understood that under the circumstances I had to perform a very extensive operation, not only removing the pectoralis major muscle, together with the axillary glands, but also exsecting so large an area of adjacent integument that a plastic operation had to be undertaken (see Fig. 7). Recovery was perfect until six months later, when a small nodule appeared at the anterior axillary fold. This was again extensively removed. Then a period of euphoria followed for a whole year. In September, 1896, a hard nodule originated near the sternum, which was also extirpated. Then there was no disturbance until June, 1897, when a small nodule appeared in the axilla, which was extirpated by Dr. F. Torek, to whom I am indebted for the following report:

On August 7, 1897, there was a pain at the site of the last operation. No recurrence. March 7, 1898, recurrence in posterior axillary line; extirpation, April 11, 1899; another recurrence, the tumor showing about 3 cm. in diameter; ichthyol-vasogen treatment. On January 16, 1900, the immovable tumor has grown to the size of 8 to 9 cm. in diameter. Dissection of axillary artery and ligation of the axillary vein. Microscopical examination by Prof. Henry J. Brooks; carcinoma, with much fibrous tissue. February 14, wound perfectly healed. February 14, 1901, another recurrence in axilla, tumor being about the size of an egg. February 19, operation. Discharged from hospital cured, March 8. August 21, 1901, another large node, probably starting from the stump of the pectoralis major muscle, which is removed. Primary union on August 29 to October 31, 1901, another operation is made in the pectoral region, and two nodules removed in the axillary region. January 13, 1902, another recurrence in the axilla of the size of a filbert; also one tumor below the clavicle, of the size of a walnut. A third neoplasm is observed in the left arm, in the former region of the pectoralis major muscle, and alongside the biceps muscle. None of the recurrent tumors is movable. Medication: thyroid extract. In view of this enormous extent of the growths, the arm also being extremely œdematous, a tenth operation seemed to be inopportune, wherefore the Röntgen therapy was considered now.

Still, it seemed to be more preferable to extirpate the tumorous portions, as far as it was possible, before resorting to irradiation. I succeeded in removing the whole biceps' muscle, and a part of the axillary region.

The infraclavicular tumor could not be removed in its entirety. The patient left St. Mark's Hospital eleven days afterward. The general condition had remarkably improved after ten irradiations, each one lasting about thirty minutes. The infiltration below the clavicle and along the triceps muscle, as well as the œdema, did not disappear until extensive dermatitis of the first degree had set in.

Similar experience was gained in the case of a lady of forty-two years, who showed the signs of sarcoma of the orbit a year ago, so that enucleation of the eye-ball had to be undertaken. Recurrence in the orbit, as well as in the superior maxilla, and the frontal bone, took place three months thereafter, and reached such an extent that it was regarded inoperable.

After having ascertained the extent of the growth by a skiagraph, I removed the diseased bone portions. Three weeks thereafter, when cicatrization had taken place, I began irradiation three times a week, exposing ten minutes each time. No change during two months' treatment was observed. But when irradiation was stopped for three weeks, the signs of recurrence showed up again, the vicinity of the orbit projecting far. Now irradiation was resorted to every day, small distance, low vacuum, and high current being chosen. After eleven exposures extensive dermatitis developed, which proved

to be of the ulcerative type, within the center of the irradiated area. At the same time complete alopecia at the diseased side set in. (Fig. 8.) The patient suffered considerably for a week, then the symptoms gradually subsided. The treatment consisted in the application of Burow's solution at first, and in the use of xeroform gauze later on. Three weeks after the beginning of the vehement dermatitis all signs of the sarcomatous infiltration, especially the projection, had disappeared and the general condition of the patient improved remarkably. There is, in fact, no abnormality noted at the present time. This state of euphoria has continued now for three months. Whether it will continue indefinitely, is, at least, doubtful; nevertheless, the entire disappearance of the recurrent growth is to be regarded a most important fact.

In conclusion, I may again call attention to the advisability of prophylactic irradiation shortly after the removal of malignant tumors.

MARITIME QUARANTINE WITHOUT DETENTION OF NON-INFECTED VESSELS FROM PORTS QUARANTINED AGAINST YELLOW FEVER.*

By EDMOND SOUCHON, M.D.,
NEW ORLEANS, LA.
PRESIDENT OF THE LOUISIANA STATE BOARD OF HEALTH.

THE remarks which follow will apply, for the present, to yellow fever only, since it is the quarantinable disease which is the greatest danger to the Southern States.

The keynote of this stride in modern scientific quarantine was struck by the Louisiana State Board of Health when it passed, on September 2, 1902, the resolution which reads thus: "Free pratique shall be given to non-infected vessels, with or without passengers, from ports where yellow fever is suspected, or prevails, *provided* said vessels are disinfected at the port of departure, or at the last port touched at, in a manner satisfactory to the Louisiana State Board of Health, *provided, further*, that said vessels upon arriving at the Mississippi River Quarantine Station shall be disinfected again, and *provided, still further*, that five full days at least shall have elapsed since the completion of the first disinfection before the second disinfection is done at the Mississippi River Quarantine Station."

These regulations are based upon the study, mostly of the records of the Louisiana State Board of Health, which show that a number of non-infected vessels have developed yellow fever after disinfection.

That non-infected vessels, *i. e.* vessels presenting no sickness at the port of departure or in transit, may develop yellow fever at the port of arrival after disinfection has been demonstrated by the writer in a paper published in the MEDICAL RECORD of December 28, 1901. These cases are due to the fact that during the stirring up of things aboard, necessitated by the disinfection, some infecting agent has been released and some non-immunes coming in contact with it are infected. The object of the second disinfection is to neutralize the effects of a possible case following the first disinfection, which case may be so light as to escape the observation of the officers of the vessels who, therefore, will not report that they had sickness aboard.

As far as we could ascertain, there is no record of a case of yellow fever following a second disinfection performed five days after the first one. There are cases following a second disinfection, but that was before five days had elapsed between the two disinfections.

The Louisiana State Board of Health has already put the principle into practice by granting free pratique to coffee ships from Brazil that will stop at Port Castries (St. Lucia) to be disinfected by an officer of the Board and then be again disinfected at least five days afterward at the Mississippi River Quarantine Station.

When the United States Public Health and Marine Hospital Service establishes floating disinfecting plants at the ports quarantined against yellow fever, to disinfect vessels before they leave, as it has done in Cuban ports, the Louisiana State Board of Health will honor its certificates of disinfection, provided a set of regulations governing these vessels shall be agreed upon between the Louisiana State Board of Health and the United States Public Health and Marine Hospital Service, which shall pledge itself to their faithful application by first-class officers. The United States Public Health and Marine Hospital Service need not have a plant at each port. It would be sufficient for it to establish disinfecting stations on the course of the vessels from the yellow-fever ports, where these vessels would stop to be disinfected at least five days before arriving at the Mississippi River Quarantine Station. Under these regulations non-infected vessels which have been at least five days in transit, since the first disinfection, *i. e.* "long-trip vessels" shall not be detained after the second disinfection. Vessels which have been less than five days in transit, *i. e.* "short-trip vessels" which have anchored 1,000 feet, more or less, away from shore, and have had no communication with shore at the quarantined ports shall not be detained, but the passengers, if any, shall be detained long enough to make five days from the disinfection at the port of departure.

The baggage of such passengers must, of course, be disinfected before being admitted on board.

Only vessels which have had connection with the shore at the quarantined ports shall be detained long enough to make five days from the first disinfection. They shall be disinfected for the second time at the end of their five days and not on the day of their arrival at the Mississippi River Quarantine Station. Whenever steamship companies will defray the expenses of disinfection at the port of departure, or at any intermediate port approved by the Louisiana State Board of Health, the same privileges shall be granted to them.

The Louisiana State Board of Health has done away with the detention of all the non-infected vessels coming from the fruit ports of Central America and of Cuba, under regulations of which the following is a résumé.

The basic principles are that fruit vessels shall not be detained at the Quarantine Station upon condition that they avoid all causes of possible infection. under regulations of the Louisiana State Board of Health.

The principal regulations are the following: (1) A resident medical inspector shall be appointed for each port. (2) Vessels shall have no communication with the shore and, conversely, except through the laborers. (3) Vessels shall carry only fruit and specified articles of freight. (4) Vessels carrying passengers shall carry a marine medical inspector on board. (5) Passengers shall not be received on board unless their clothing and baggage have been previously disinfected. (6) Vessels not carrying passengers shall not be disinfected nor detained at the Mississippi River Quarantine Station. (7) Vessels

*Read at the meeting of the International Sanitary Conference at Washington, December 2, 1902; also read at a meeting of the Louisiana State Board of Health, September 25, 1902, and officially endorsed by resolution of the Board.

with passengers shall be disinfected; and the passengers shall be detained long enough to make five days from the last port touched, but the vessel shall not be detained. (8) Vessels from infected ports shall all carry marine medical inspectors, those not carrying passengers, as well as those carrying passengers. (9) They shall all be disinfected at the Mississippi River Quarantine Station. (10) Passengers from infected ports shall be detained at the Mississippi River Quarantine Station five days after the arrival at the station, but the vessel shall not be detained. (11) Infected vessels shall be disinfected and shall be detained with all on board five days at the Mississippi River Quarantine Station after the completion of the disinfection, and the removal of the last case of yellow fever from the vessel. (12) Agents may send lighters down to the station to bring the fruit to the city. (13) The detailed regulations define precisely the duties of each of the officers of the Board of Health and those of the fruit companies, thereby excluding all pleas of ignorance of the exact meanings of the Board.

Fruit vessels which have left a port declared infected before they had time to place a medical inspector on board, upon arriving at the Mississippi River Quarantine Station, shall be disinfected, the regular crew removed, a new crew placed on board, except the master and engineer, and they shall be allowed to unload at the wharf in the city.

ON THE SOLARIZATION OF THE NUDE BODY BY THE SUN AND ELECTRIC ARC LIGHT RAYS, AND THE PHYSIOLOGICAL AND PHYSICAL INFLUENCE OF THESE RAYS UPON IRON PREPARATIONS AFTER THEIR INTERNAL ADMINISTRATION.

By J. MOUNT BLEYER, M.D., F.R.A.M.L., LL.D.,
NEW YORK.

I BRING before your notice one of the physical marvels which light rays are capable of producing upon the salts of iron, without and within the human body, or upon vegetation.

This physiological discovery has been followed up closely in its various aspects, and, as a conclusion, I found that in the administration of iron salts, in connection with the exposure thereafter of the human body to sunlight, or the electric arc light, an immediate physical and physiological change takes place, making it possible for metabolism to do the rest of the work, with results that are far-reaching and remarkable.

It is a noted fact that photographic chemistry has taught us much in many respects. We are indebted for nearly all the facts connected with the photographic properties of the salts of iron to the labors of Sir John Herschel. In his hands these salts have become valuable photographic agents, and two or three processes which have been devised are among the most interesting within the range of the photographic art. These various processes can be referred to in the many works on photography, where the whole detail can be accurately studied.

I have found that nearly all the salts of iron, under the influence of the sun's rays, or under the electric arc-light, for a longer or shorter period of exposure, undergo changes. Herschel found this fact: Papers washed with the ferro-sesqui-cyanide of potassium, exposed to the prismatic spectrum, proved that the decomposition of the salt and deposit of Prussian blue is due to the action of the blue and violet rays, below, the blue having absolutely no influence. The greatest activity appears to exist about the region of the indigo rays. The rationale of these different processes in photography has been well explained by Herschel. In nearly all cases the action of the sun's rays is a deoxidizing one. In the case of the ferro-sesqui-cyanide-of-potassium process, in which the paper simply is washed with the ferro-sesqui-cyanide of potassium, it is found highly sensitive to light. Exposed to sunlight for about an hour or less, with an engraving upon it, a beautiful negative photograph is the result. Really what happens physically is that oxygen, which combines with hydrogen to form water, is parted with. Prussian blue is deposited, the base being supplied by the destruction of one portion of the ferrocyanic acid, and the acid by the destruction of another. Herschel says: "It seems natural, at first sight, to refer these curious and complex changes to the instability of the cyanic compounds; and that this opinion is, to a certain extent, correct is proved by the photographic impressions received on papers which have no iron but that which exists in the ferrocyanic salts themselves. Nevertheless, the following experiments abundantly prove that in several of the changes above described the *immediate action* of the solar rays is not exerted on these salts, but on the iron contained in the ferruginous solutions added to them, which it deoxidizes, or otherwise alters, thereby presenting it to the ferrocyanic salts in such a form as to precipitate the acid in combination with the peroxide or protoxide of iron, as the case may be.

To make this evident, all that is necessary is simply to *leave out the ferrocyanate* in the preparation of the photographic paper, which thus becomes reduced to a simple washing over with the ammonio-citric solution. . . . If a slip of this paper be held for four or five seconds in the sun, or arc-light (the effect of which is quite imperceptible to the eye), and when withdrawn into the shade be washed over with the ferro-sesqui-cyanate of potash, a considerable deposit of Prussian blue is formed on the sunned or exposed part, and none whatever on the rest, so that on washing the whole with water a pretty strong blue impression is left, demonstrating the reduction of iron in that portion of the paper to the stall of protoxide. The effect in question is not, it should be observed, peculiar to the ammonia-citrate of iron. The ammonio-potassium-tartrate fully possesses it, and the perchloride, exactly neutralized, partakes of the same property; but the experiment is far more neatly made, and succeeds better, with other salts.

If this salt is mixed with perchloride of iron and washed over paper, whilst it is exposed to the spectrum, the action is continued down to the very end of the thermic spectrum. The formation of the deposit color in this region is accompanied with phenomena of a novel character, referable to the heat developed by the thermic spectrum. Oval brown spots are formed which correspond with the heat spots referred to, and which are evidently due to calorific agency. If ammonia-citrate of iron is used instead of the perchloride, "a copious and richly colored deposit of Prussian blue is formed over the whole of the blue, violet, and extra spectral rays in that direction, extending downward (with rapid graduation) almost to the yellow in the spectrum. If the action of light is continued, the blue and violet rays, in a very strange way, destroy their own work. "A *white* oval makes its appearance in the most intense part of the blue, which extends rapidly upward and downward. At a certain point of the action the upper or more refrangible extremity of the white impression exhibits a semicircular termination, beyond which is a distinct and tolerably well-defined congregate image, or insulated circular

white spot, whose center is situated far beyond the extreme visible violet."

My researches, as far as they have gone, show that all the per-salts of iron are converted into proto-salts by exposure to sunlight and the electric arc-light rays, when in combination with organic matter. This fact has been most fully confirmed, and even in soils all the per-salts are changed to proto-salts of iron by the action of growing vegetable and light. I have reasons for believing that all the proto-salts undergo some change. What this change may be it is impossible to say at the present stage of the inquiry, but it will be seen that scarcely any of the metallic salts resist the agency of the sun's or arc-light rays.

It was these facts that first led me to undertake a number of physiological experiments to test the value of the different salts of iron in conjunction with light administration. In over one hundred tuberculous and anæmic patients the different iron salts and organic preparations of iron were administered, and the patients placed daily in the way of the sun's and electric-arc-light rays. Much to my surprise, I found that the iron salts (organic iron preparations) were taken up most rapidly, showing marvelous constitutional effects. After the first week's trial the blood counts proved their richness in number to an enormous amount, as compared with previous counts by the older methods of administration, and with other preparations by the old method. The hæmoglobin increase was a very marked condition.

In this concise paper, for the first time since my experimental work, I bring this new method before the notice of my colleagues, knowing of nothing more powerful that will assist in supplying iron to the system more rapidly than usual, in cases in which it is indicated, than this mode of administering salts of iron in combination with light rays. We also know that iron in various forms is being introduced daily into the system, by many articles of food; light effects these forms of iron in exactly the same manner as if it were taken in the form of the salts. It is often a good plan, where it is feasible, to allow the eating of such articles of foods and vegetables as much as possible. I have taken notice of this fact in a number of cases, and must say very satisfactory results have been obtained. Amongst the different forms of iron and its compounds that I made use of in my investigations were the Blaud's pill in capsule, in a fresh state, the ammonia-citrate of iron, carbonate of iron, tincture chloride of iron, and several other preparations, as tropon. This organic compound with iron was selected by me upon its merits. I found it contained vegetable and animal material in such a state as light rays would, perhaps, have a rapid action upon. Much to my surprise, I noticed that this organic food with an iron preparation showed important therapeutic results after a very short time. It also gave the least digestive disturbances as compared with the others. I found also a very simple way to administer iron with rapid showings—in the hard-boiled egg, and the iron powder, or Blaud's moss, sprinkled upon it. This was almost an ideal result. All iron preparations exhibited in connection with light rays left, beyond a doubt, their physiological workings

836 Lexington Avenue.

Isolation in Scarlatina.—Millard quotes the principal health officers to prove that the general idea of the infectiveness of scarlet fever desquamations is greatly exaggerated. If his conclusions are correct, we may reduce the long period of isolation.—*Lancet.*

A TREATMENT FOR SPINA BIFIDA, WITH THE HISTORY OF A CASE.

By FREDERIC GRIFFITH, M.D.,
NEW YORK.
SURGEON, BELLEVUE DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

The following is the history of a case which, while apparently going on to a successful issue, was fated to terminate suddenly in failure from an untoward accident upon the part of the caretaker. The patient, a little female infant, was born in the middle of January of the present year of healthy parentage. The family history of the present generation is, however, unfortunate, but would seem rather to be due to ignorance of the proper care of children upon the part of the mother than to direct disease influence. The mother had given birth to nine children during her married life, of whom five had died before the age of five years. One had been born with a congenital hernia. At the time of the birth of the child under consideration, a woman friend noticed a soft, hollow spot in the small of the back covered with white skin; the midwife in

attendance, however, stated that it was of no consequence. The child was born at full term, and otherwise normally formed.

Directly after birth a tumor formation rapidly took place from over the lower third of the back. As soon as the mother was able to be about the child was taken to a hospital in the suburban city in which she lived. Here, after examination, the diagnosis of spina bifida was made, and the opinion given that the case was hopeless from the standpoint of operation, and that the chance of long survival was slim.

From the age of three weeks, when the child first came under my observation, up until its death, it was under my continual care. At the first visit, upon examination, the child appeared of firm flesh, fair color and healthy. The body was well formed, head of average size, the fontanels not bulging. The child was breast-fed, regular and normal as to bowel and kidney action, and the mother, almost from the first, took it up but once

*Presented at the New York Academy of Medicine, Surgical Section, October 13, 1902.

during the night to nurse. The baby was of good temper, seemed bright, and was thriving.

Extending up from over the last lumbar vertebra to the tenth dorsal was a tumorous growth. The base was broadly attached and fifteen inches in circumference at the junction with the child's body, and three inches high. The covering seemed like stretched parchment, giving the appearance of translucency at the top and grading off to a normal skin covering at the sides and base. The top was flattened somewhat, and ulcerated, so that rupture seemed imminent. While the tumor was tense, it rose and fell with respiratory movement. It was tender to the touch and the child slept and was carried upon its side.

Repeating to me the medical opinion which had been given, I could say little to console, and my advice provided simply for a provisional treatment in case of rupture of the sac wall, besides giving general directions. To the ulcerated surface I applied boric-acid ointment spread on patent lint, cotton batting, and the whole held on by a broad muslin bandage for protection and support.

The child did well under this treatment, the ulceration healing kindly, and I began to plan active measures for the relief of the malformation.

The child was three months and three weeks old when a drop of clear fluid upon the apparently unbroken sac surface warned me that despatch was needed if I was to command any operative procedure. Preparing for the operation, the child was wrapped in two blankets, leaving the tumor and portion of the back exposed, while the upper and lower halves of its body were warmly covered. The operating table was constructed by placing a broad, flat-backed chair, tilted with legs in the air, upon the kitchen table. A pillow was flattened upon the chair-back, and the child laid head-down upon it. Held in this position by having its legs bound to the chair-rung by a muslin bandage, I provided against the loss from the brain of too great a quantity of the cerebrospinal fluid. My friend, Dr. Hinmers, administered the minimum quantity of ether upon a small, hollow towel cone. I employed ether as the anæsthetic, because of its slower action upon the vital centers.

With a small trocar and cannula I punctured over the upper and right side of the tumor and drew off slowly six ounces of water-like fluid. Enlarging the puncture with scissors into an incision parallel with the spine, four inches long, the sac was completely opened. The walls were thick at the sides and bottom, as though the muscles of the back had been pushed aside and dissected. At the bottom of the unilocular chamber was a sunken circular orifice one inch and a half in diameter. This was filled up with membranous tissue, through which appeared, at the lower portion, what I took to be the stump of the spinal cord; it was accompanied by a small artery, which had been severed, requiring a ligature to control the bleeding. Upon the opposite side of the trunnelled, celery-like stalk was a hole in the membranous diaphragm one-eighth of an inch in diameter, from which watery fluid welled with every respiratory movement. Feeling gently the edge of the circular excavation—for it had now sunken, becoming like a reversed watch-crystal—with the tip of my finger wrapped in sterile gauze, I was enabled to make out a bony margin. The location would correspond to the situation of the spinous and lateral processes of the third lumbar vertebra, though it extended more to the left side of the middle line than to the right, and was evidently the original site, as had been determined at the child's birth.

Trimming away the sides of the walls upon either side until they could be brought loosely together, thus allowing for retraction of the parts to take place; the child at this stage appearing to do badly, I stopped the anæsthetic, finishing the operation without its aid. Believing that I was not justified in attempting any osteoplastic work, or even to meddle with the end of the cord, which appeared bound to the lower edge of the bony framework, owing to the general condition of the child, I quickly brought the side walls together over a piece of sterile gauze packing, and sutured with light catgut along the middle line, withdrawing the gauze before tying the last sutures, attempting by this means to secure a dry wound.

The dressing consisted of gauze, held on by broad straps of adhesive plaster, passing two-thirds the way round the body from the buttocks to beneath the shoulder blades, with an outer muslin bandage.

The child had been in an inclined position, head down, of forty degrees, during the operation, without any apparent ill effects as shown by heart or respiratory action. It was put in a bed in the same relative position.

Reaction was prompt; the child had kept its body heat and appeared comfortable, soon became quiet, taking the breast half an hour after having been put to bed, though the ether caused vomiting to take place.

Flushing of the face did not occur at any time. My directions being that this condition, if it arose, was to be combated by elevating the child to a horizontal level upon its belly until it should subside, when the former position was to be resumed.

The first night the mother reported that, while the child was wakeful, it had remained quiet. Toward the next evening and during the second night, it was fretful and twitched its hands. The child was taken down from the incline and carried, with the head a little lower than the horizontal, in its mother's arms all that night.

The evening of the third day the child was reported to be failing, as the twitching had continued and three "spasms," though light in character, had occurred. The fourth day I found the child doing well; it was bright, and followed the movements of my hand, circling about its head, with its eyes, but after a turn or two became irritated by the effort and fretted. I changed the dressing at this time, and found a wound healing by primary union; applying a gauze dressing braced with thin wooden splints and padded with cotton, the whole being held by means of plaster straps and bandage.

The child had slept for sufficient intervals, after the first night, for all requirements. Its bowel movements were normal and kidney action free. While it was at times too weak to draw milk fast enough for its wants and became fretful thereby, it was fed by warmed drawn milk from a heated spoon, and drank, in addition, water, at regular intervals.

The anterior fontanelle, which had sunken somewhat, was again filling out flush with the scalp; the cause of the previous retraction was due, I believe, to the siphonage action of the gauze of the first dressing upon the spinal fluid. While gauze will not drain pus, it will suck up watery fluid such as this was, and which explained the presence of moisture upon the child's back between the shoulders noted and reported to me the first and second nights. The threatening symptoms which occurred at this time seemed to be accounted for upon the same basis. It seems highly probable that, had not the inclined position been kept, the

child must certainly have died from excessive drainage of the cerebrospinal fluid.

The unfortunate incident which closed the life of my little patient occurred upon the fifth day after operation. The mother accidentally let it fall from her arms, and in the wild scramble which ensued to keep the child from striking the floor, it was badly shaken up and rapidly revolved in the air. This was fatal, for, from a hypersensitive body still in the balance, it rapidly sank in a collapse and died in a few hours.

An autopsy was refused, but an examination of the fluid contents of the sac, which had been saved after withdrawal, showed a clear, limpid, unclouded watery fluid, having a specific gravity of 1022, alkaline in reaction and of a salty taste. The reaction for albumin by the boiling and by the ring nitric acid tests was prompt. Sugar was also present, as has been pointed out by Halliburton, by the copper test. Microscopically, the fluid was clear, with a few granular cellular elements floating free.

The cause of spina bifida, according to the committee of the London Clinical Society that reported in 1885: the anatomy of spina bifida assumes a primary defect of development of the mesoblast, from which the structures closing the vertebral furrow are developed. After the closure of the neural furrow, it would appear that the processes of mesoblast, which subsequently insinuate themselves between the primitive spinal cord and its overlying epiblast, are formed in an insufficient degree to meet and combine. The report, continuing, states that involvement of the cord, of which my case was an instance, occurred in 95 per cent. of the known cases.

Three varieties of this malformation are recognized, according to the relation which the cord bears to the sac walls. As my case consisted of a stumped cord coming through a thin, perforated diaphragm, which seemed to have been the original cord membranes, the case may be designated as that form of spina bifida known as meningomyelocele. According to statistics, 50 per cent. of cases of spina bifida have their original site in the lumbar region.

From a study of this case, I shall in future feel justified in attempting more or less active operative procedures, bearing always in mind the delicacy of the subject, but am impressed with the value of the inclined position in the treatment of these cases. Slung by the legs, assisted by the child's nightgown, drawn together below the feet, thus equalizing pressure, the child will be found to have adequate movement upon the face or side. Nursing and all necessary toilet procedures can be readily accomplished in this position. So held for a varying period, according to circumstances, until healing is well established, greater hopes for successful issue seems to be made possible. To overcome the siphon action of dressings, it would seem advisable to hermetically seal the area surrounding the wound from the rest of the dressing by means of rubber tissue, dissolved about its edges by chloroform or by collodion upon cotton.

805 Madison Avenue.

The Causation of Epilepsy.—Heretofore great uncertainty prevailed as to the cause of epilepsy, but the investigations of Mr. Bea undoubtedly throw some light upon the subject. Numerous blood examinations show the constant presence in the blood of a minute parasite just before an attack. The parasite looks like a small point, which moves rapidly, and sometimes forms into chains which become attached to red corpuscles.

Clinical Department.

A CASE OF CARBOLIC-ACID POISONING.

By G. G. MARSHALL, M.D.,
WALLINGFORD, VT.

The patient was a man seventy-four years old, who had been gradually failing in strength for some six months, and for the last three months had been confined to the bed, requiring the constant attendance of a nurse. The only evident cause of his growing weakness was arterial sclerosis, though a small amount of albumin had been found in the urine at times. But as there was more or less pus in the urine, requiring irrigation of the bladder at least twice a day, we were never sure that the albumin came from the kidneys. This was the condition of our patient when the accident occurred. About 3.30 P.M., on October 22, the nurse prepared to throw into the bowel, through a rectal tube, which was introduced about twelve inches, four ounces of sweet oil and two tablespoonfuls of glycerin. When this had been done, the patient complained of a prickling sensation in the rectum. The nurse then returned to the bathroom, and there she noticed that she had poured from the bottle of carbolic acid instead of the glycerin. She then immediatey irrigated the bowel with two quarts of water, which returned freely, and as it returned, the odor of carbolic acid was strong. And as the return water came in contact with the nurse's hand, it burned it and also the skin of the patient, so that the skin over the hips was discolored for several days.

In about five to eight minutes the patient began to fail rapidly in strength, and was soon helpless. The pulse became very weak and irregular, and in about two hours no pulse could be detected at the wrist. The patient's mind became dull in five minutes from the time the acid was given, and in fifteen minutes he was unable to answer questions, and did not realize what was going on. Both eyes remained widely open with pupils contracted. The eyes moved strangely, as though he was about to go into a convulsion. The lower jaw dropped, and the tongue slightly protruded with the tip pointed up, waved from side to side with marked regularity. The breathing was heavy and quite regular.

Perhaps ten minutes after washing the bowel with the water, the nurse remembered the use of alcohol in carbolic-acid poisoning, and then she introduced through the tube, inserted high up, about four ounces of alcohol with an equal amount of water. Then she again irrigated freely with water, and after this with milk.

During the first ten minutes the patient was given some brandy, but soon he was unable to swallow.

I saw the patient about forty-five minutes after the accident had occurred, when I assisted in again washing the bowel with alcohol and water, about six ounces of each. This was repeated once, and then the bowel was again irrigated with milk. Strychnine and digitalis were given freely, and then repeated hypodermics of brandy were given, together with nitroglycerin. The skin was cold and moist, so atropine was given. All of these had not the slightest effect in stimulating the heart, and as the patient was apparently dying, we were about to abandon further efforts, when at about 6.30 there was noticed a slight quiver in the radial artery. The hypodermics of brandy were repeated, and by 7 P.M. the pulse was quite perceptible. From this time on the symptoms gradually improved, and by 11 P.M. the patient had sufficiently recovered consciousness to call for a bed-pan, and he then had a normal stool. During the next two days hypo-

dermics of strychnine were required to keep up the pulse, but there was a slow and steady gain in strength and general condition. The urine showed the smoky color by noon of the next day and continued to do so for about thirty-six hours. In about five days the patient had gotten nearly back to where he was before the accident.

One peculiar point of interest was noticed about the urine, which, as has been noted, had contained more or less pus, and had also had a very offensive odor, but since the poisoning the pus has disappeared and the urine has no odor.

There has been no amount of soreness of the bowels, and no pain from the movements, which have been frequent. Some of the time he has complained of a throbbing in the rectum. The patient has no knowledge of the accident, and does not suspect that he has been so low. At the present writing, about eight days after the accident, the patient is very weak, but there appears to be no other after-effects of the poisoning.

THE HEREDITARY INFLUENCE IN NYSTAGMUS REMARKABLY ILLUSTRATED.

By ISAIAH FRANK, M.D.,
NEW YORK.

ASSISTANT OUT-DOOR EYE DEPARTMENT, BELLEVUE HOSPITAL; ASSISTANT NEW YORK POST-GRADUATE HOSPITAL EYE CLINIC; ASSISTANT NEW YORK EYE AND EAR INFIRMARY.

Binocular adjustment is learned by the child at the same time with the judgment of fixed objects, with the development of conscious vision, and the recognition of objects and processes of motion. The necessary fibrous connections between the retina and celebral cortex, between the fovea centralis and the perceptive center, only develop fully after birth, and gradually become medullated and thus capable of function. If this development is disturbed for any reason—for example, by early-acquired opacity of the refractive media, by the impossibility of perfect vision on account of congenital influences or anomalies, etc.—then a peculiar disturbance of movement, viz., nystagmus, is constantly noticed. By its conjugate occurrence, this points to a cause which is situated centrally from the muscle nuclei. Hence, nystagmus may be defined as imperfect cortical innervation of the voluntary muscles of the eye, as a peculiar form of cortical paralysis agitans.

This brief introduction will make clear the possibility of heredity in nystagmus, as conclusively evidenced by the following remarkable case: Mr. D. W. W. had nystagmus. He married twice. By the first wife he had one daughter, now a Mrs. R. Mrs. R. has fourteen children, one of whom has nystagmus. By the second wife he had five children, as follows: Mr. M. W., who has two children; Mrs. B. Z., who has three children, one of whom has nystagmus; Mrs. B. A., who has seven children, one of whom has nystagmus; Mrs. B. M., who has three children, three of whom have nystagmus; Mrs. D. B., who has nystagmus herself, has one child. Thus we see that Mr. D. W. W., who had nystagmus, had one child and six grandchildren with the same affection.

The important and characteristic point is that a grandchild of the first wife and several grandchildren of the second wife show the hereditary influence; that is, the same father has transmitted the nystagmus, or rather the causative factor thereof, to the offspring of the two different mothers. While nystagmus is generally recognized as being hereditary, *i. e.* in congenital cases, I can find no record of a case in which the transmission was through different parents; and for that reason this case is noteworthy.

130 East Sixty-fourth Street.

A CASE OF ECLAMPSIA.

By P. P. M. JORGENSEN, M.D.,
KENOSHA, WIS.

On September 26, 1901, I was first called to see Mrs. J. C. P., age thirty-five years, family history negative. Had two living children, eight and eleven years of age, respectively. She stated that she had always been in good health and she looked the picture of health at this time. Since the birth of her last living child she had had three miscarriages; each one coming on spontaneously without any great amount of previous disturbance.

She believed herself about two months pregnant at the time I saw her, and was suffering from a slight amount of nausea and distaste for food. Although the symptoms were not very severe, yet she wanted herself attended to, as she was very anxious to carry the child to term. I prescribed a few of the usual nausea powders and a bitter tonic, which relieved her in the course of a short time so that she was able to enjoy her meals and was feeling well in every way.

January 7, 1902, I was once more summoned to her home. This time she was still looking well, and said she felt well excepting that she had a great deal of pain in the rectum when her bowels moved, which I found was caused by a slight fissure. A simple ointment, in connection with a mild laxative, soon relieved this condition.

January 25, 1902, or about the end of her sixth month of gestation, I saw her again. At this time the husband sent for me one Saturday evening, although she protested it was a useless expense, as she was able to attend to her own housework, and had only felt slightly indisposed for three or four days, with some swelling of the feet in the evening. On examination I found the lower extremities markedly œdematous and some puffiness under the eyes. I scented trouble and at once sent her to bed, and gave a big dose of calomel, followed by a saline in the morning.

I secured a specimen of her urine, which I found on analysis contained almost no urea, but, on boiling, formed almost a solid chunk of coagulated albumin.

During the next day (Sunday) she developed a severe headache, and in spite of the fact that I put her on an absolute milk diet, kept up the purgation, and likewise kept the skin active, the uræmic symptoms gradually grew more marked. By Monday morning vision was beginning to fail, although I was still working the eliminative plan as thoroughly as I could. Monday noon she had a severe convulsion. It now became plain to me that the only chance for the woman's life was in emptying the uterus as soon as possible.

With this object in view, I made an attempt to bring on labor by introducing a stiff-rubber catheter up into the uterus about six inches, passing it carefully between the membranes and the uterine wall, and packing the vagina with gauze to retain it. I re-introduced the catheter and changed the packing in about three hours, and still I waited in vain for any expulsive manifestations on the part of the uterus.

Monday evening I had Dr. Kimball give her some chloroform, while I attempted manual dilatation with my fingers, but found the cervix so strong and rigid that after working for twenty minutes my fingers grew so tired and numb that I was obliged to desist without having gained any headway.

My consultants advised me to try dilatation with Barnes' bags, and this method I kept up at intervals for eight or ten hours without any effect whatever. By Tuesday evening, seventy-two hours after my first visit, the uræmic symptoms had developed to so

alarming a degree that the patient was unable to destinguish an object at a distance of two feet in front of her eyes. I now boiled my instruments, determined to deliver the woman, no matter if the unyielding os did tear. The people were unable to get their former consultants at this time, so I called Drs. Cheever and Van Westrienen, and with their very efficient assistance I once more set to work. After putting her under the influence of chloroform, we used the Goodell's dilators to start with, and as soon as we were able to introduce two fingers of each hand, we pulled the uterus down as far as possible, one holding it while the other caught hold with both hands and made traction in opposite directions until he was tired out, when the other would take hold. In this way we succeeded in delivering the woman of a good-sized, six-months fœtus, without any marked laceration of the cervix. The placenta was delivered, and by manual manipulations we succeeded in causing the womb to contract, so that the hemorrhage was not very marked. The patient, of course, was in a pitiable condition for the next few days, and yet there was steady improvement from the very first day after the uterus was emptied. There was no infection, or other ontoward symptoms, outside of the fact that she bore calomel rather poorly, causing a very sore mouth for a time.

The last time I saw the patient was in July. She was at that time looking and feeling as well as ever, although her vision had not been entirely restored, and there was still some albumin in the urine.

THE TREATMENT OF DISEASES OF THE LIVER.

By DR. H. RICHARDSON,
BALTIMORE, MD.
PATHOLOGIST, MOUNT HOPE RETREAT.

The liver, being the largest organ of the body, performing a multitude of functions of the greatest importance to the well-being of the organism, it is of the utmost importance that it should be maintained in as high a state of efficiency as possible. These various functions are described as proteolytic, glycogenic, metabolic, and biliary, the bile acting as an excretive, and, in the intestine, as a digestive. It is an accepted fact that any organ which fails to excrete its waste products soon becomes unable to functionate properly, and therefore the quantity and quality of the bile are of the greatest importance. There are, presumably, several active principles formed in the liver, some of them, at least, of the nature of ferments, such as the aldehydase of Jacobi, which take an active and essential part in metabolism; of these little is known, but their formation and activity must depend largely on the biliary secretion.

All the most recent experimenters are unanimous in their results as to the inutility of the so-called cholagogues of the pharmacopœia, all agreeing that they fail to increase the flow of bile, and they also agree that the bile salts, viz., the glycocholate and taurocholate of sodium are the only substances which will increase the quantity of biliary excretion.

Gallstones are usually the result of bacterial invasion of the gall-bladder, coupled with the precipitation of cholesterin and of the coloring matters, which can only take place when there is a deficiency of the bile salts which hold these substances in solution. Obviously, then, the treatment of gallstones is to supply sufficient bile salts to hold these substances in solution. Even after the removal of gallstones by operation, it is by no means uncommon for a reformation to take place. Glycocholate of sodium, administered over a lengthened period, will often dissolve small stones *in situ*, and will prevent their formation; therefore, it is advisable for a patient who has been operated upon to take the glycocholate of sodium at frequent intervals to insure against the return of the disease. Gallstones are much more common than is usually supposed, occurring in about 10 per cent. of women and 5 per cent of men.

Hepatic troubles are constant with high livers and alcoholics, as well as among people of sedentary habits, the liver being overworked to begin with, while the want of exercise causes a deficient circulation and consequent congestion of the organ. In these cases the glycocholate is of great service, acting as a purge to the liver. Especially is this mode of treatment indicated in those forms of chronic malaria in which the liver becomes enlarged and the skin takes on that ieteroid hue which is so common in those sections of the country where malaria is rife.

In the intestine the bile acts as an emulsifier, increasing the absorption of fats. Many cases of malnutrition are due to an insufficient absorption of fat due to an insufficient supply of bile; the very small quantity of fat absorped during occlusion of the gall-duct, or biliary fistula, has been often observed. In diabetes, when a patient is on a diet in which carbohydrates are reduced to a minimum, and fats given as a substitute, the administration of glycocholate of sodium will, in many cases, overcome the repugnance of the patient to the large quantities of butter, oil, and fat prescribed in a few days. In Dr. Russell's very successful treatment of tuberculosis by the fat diet, the absorption and catharsis can be materially increased by the administration of the drug.

The bile is usually considered to increase peristalsis, and also to precipitate incompletely digested proteid, and so to aid digestion. In chronic constipation the drug is often of great service; many of these patients have the purgative habit, which decreases the quantity of bile; under normal conditions nearly the whole of the bile salts are reabsorbed from the intestine, returning again to the liver to be reutilized in the formation of bile. In purgation this reabsorption is interfered with, the bile salts being carried on and excreted with the fæces, and consequently the bile formation is decreased. After the administration of glycocholate of sodium for a few weeks, many of these patients are able to do without purgatives.

It is rarely necessary to give more than five grains three times a day, or, at the most, ten grains. Smaller doses than five grains are not of much use unless extended over a long period. The drug should be administered in capsules, using magnesium oxide as the excipient. Occasionally the patient may suffer from nausea after taking the capsule, but this usually passes off in a few days if the medicine is persevered with. Rarely it produces a profuse diarrhœa for a day or two, when the stools become normal.

Child Labor.—In the last few years much study has been given to the effects of fatigue upon the child. The deleterious results of overwork, mental or physical, have been noted in various ways in the growing child—studies which show the loss of mental concentration from being in school a few hours each day, with its diversified interests. More apparent are the effects of fatigue upon the physical well-being of the child. We know empirically that fatigue lessens very markedly the power to resist infections, and a closely maintained attention is just as potent a factor in producing fatigue as is physical work.—*Pediatrics.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 31, 1903.

THE SUBCUTANEOUS USE OF FORMALIN.

EVER since the relationship between septic processes and bacteria has been recognized, clinicians and pathologists have been hoping to discover some substance by the use of which, when introduced into the circulation, these processes might be controlled and the vital activities of the bacteria inhibited. There have been many experiments, and several different germicidal substances have been tried, but time has almost always conclusively shown that any antiseptic substance powerful enough to kill bacteria in the blood is also active enough to interrupt the physiology of the blood-cells, with the obvious result of killing the patient. In addition to this, we know now that it is the toxins developed by the bacteria, and not the bacteria themselves, which are responsible for the violent symptoms in septic processes, and that although we might kill all the bacteria or suspend their action, we should not thus necessarily remove the symptoms, since the toxins would still be present, exercising their poisonous action upon neural, epithelial, and muscular protoplasm. It is true that the pathologist draws a well-marked line between forms of infection in which toxins alone cause the symptoms and those in which the bacteria themselves are present in the blood; but practically such distinctions are more interesting than valuable, and the clinician must almost invariably fight a mixed condition. Another point to be remembered is that by the time that bacteria are demonstrable in the blood, there has been a very considerable formation of toxins which, as we have said, are more actively harmful than the organisms which produce them.

With these facts before them, investigators have sought rather for a substance of antitoxic power than one which could be used in the circulating blood as a germicide, and though our success so far has not been great there are some points of encouragement. Up to the present our failure has not been so complete as in our search for a germicide which will destroy bacteria in the blood and not damage the corpuscles.

The recent announcement in this city of the successful use of a weak formalin solution injected subcutaneously in a case of severe puerperal sepsis, followed by reports of other cases not so successful, has attracted much attention both in the profession and out of it. We have known for some time that formaldehyde is an antiseptic of great power, and it has been used more or less successfully in a variety of conditions, but the consensus of opinion seems to have been that, while it is extremely active, it is too irritating to be used in any degree of strength in contact with delicate tissues. The report from careful observers in this city that they had used considerable quantities of a 1–5,000 solution subcutaneously, or intravenously, with what seemed to them good result, and certainly without causing any immediately apparent damage to the blood, certainly gave rise to much interest in the profession, and to some excitement in the daily press. However, the observers themselves will undoubtedly readily admit that one or two cases prove practically nothing, and those of us who have read the reports will be very loth to admit that any startling advance has been made. The first case reported was evidently in a very bad way from a uterine streptococcus infection, with a temperature of 108°, and after the formalin injection there was a rapid fall in both temperature and pulse, followed by several performances of the same kind, a second injection of formalin meanwhile having been given. The argument of the observer was *post hoc propter hoc* as regards the injection, but it seems to us entirely too early to draw any justifiable conclusions in favor of the efficacy of the treatment, in spite of the fact that the bacteriological condition of the patient's blood improved rapidly. The violent extremes of temperature which this patient exhibited are not uncommon in severe cases of sepsis, and occur without treatment, or after the subcutaneous use of salt solution and other forms of treatment; and we must remember that the uterus in this patient had only very recently been cleared thoroughly of its septic contents when the formalin was used, so that any good effect from this intrauterine treatment might also have been expected to manifest itself at about the time when the amelioration of symptoms began. The other cases reported are still too incomplete to discuss fairly, but we may note that in one an injection of only 100 c.cm. of a solution of formalin made by mistake—1–2,500 instead of 1–5,000—caused very serious collapse with cyanosis, symptoms which we are constrained to consider due to a poisonous action upon the red blood-cells. If we are justified in this belief, the margin of safety is evidently very narrow and the need of extreme caution is very clear. The announcement in the lay press of a new procedure in medicine or surgery is always followed by much discussion, and often by a good deal of, perhaps, injudicious experimentation, into which medical men are sometimes practically driven in their relations with the enthusiastic layman. It is, therefore, wise to emphasize the importance of an accumulation of evidence, and to await the results of more cases. We know so far that considerable quantities of formalin can be injected into the human circulation with reasonable safety, and in one or two instances the injection seems to have been followed by benefit; but we are not in the possession of a real cure for septicæmia, and shall not be until we get a true antitoxin and not a mere germicide.

THE PLAGUE IN SAN FRANCISCO.

The history of the plague in San Francisco provides curious reading, and is a trenchant commentary on the manner in which politicians are able to conduct the affairs of an American State. Since the announcement was first made some three years ago that plague existed in the Chinese quarter of San Francisco, an air of mystery has been thrown over the whole circumstances. Bacteriologists — including such well-known men as Professors Simon Flexner, F. G. Novy, and Lewellys G. Barker, Drs. Kinyoun, Craig, Rosenau, and Geddings—have all declared, after careful investigation, that plague was undoubtedly present in San Francisco, and that radical measures ought to be adopted for its extinction. Instead, however, of acting upon the advice of these experts, an influential section of the commercial hierarchy of California boldly denied the trustworthiness of the conclusions reached by the visiting bacteriologists. Indeed, it was coolly asserted that one and all of these trained and experienced scientific men had made a mistake, and that, as a matter of fact, there never, at any time, had been plague in San Francisco. For three years this game of cross purposes has been going on, bacteriologists have gravely stated that plague was present in San Francisco, while the Governor of California, representing the political and commerical interests, has as solemnly asserted that the Chinese quarter of the Pacific coast city had been grossly maligned, and that San Francisco was as innocent of plague as London or New York.

During the progress of this farce, the report has gone forth at intervals that a number of persons have died in San Francisco from the loathsome disease, and that it was on the increase. Although, of course, under the circumstances, it has been difficult to arrive at the exact truth, the report has been sufficient to cause a considerable amount of alarm in the other States of the Union. On January 19 a conference of State boards of health was held at Washington to consider the plague situation in San Francisco, and to devise means to put an end to the anomalous state of affairs prevailing there. Nineteen boards of health took part in the conference, and it was virtually decided that unless the State and city authorities quickly make up their minds frankly to recognize the true situation, and to take energetic measures to extirpate the plague, the aforesaid boards of health will declare a quarantine in their respective States against California. The Governor, in his zeal for the commercial welfare of his State, has been allowed to run counter to public opinion too long. The plague in San Francisco is to some extent a distinct menace to the health of the entire community, and is in truth a matter of national concern. If necessary, Chinatown should be completely wiped out.

Prize for an Essay on Tropical Skin Diseases.— A prize of the value of £10 is offered by the *Journal of Tropical Medicine* for the best account of "Epiphytic Diseases of the Skin Met with in the Tropics." The competition is open to all qualified medical practitioners of any nationality, and essays may be written in English, French, German, Spanish, or Italian. The papers must be sent by October 1, 1903, to *The Journal of Tropical Medicine*, 83 Gt. Titchfield street, London, W.

THE ARMY CANTEEN.

In the *North American Review*, January, Major Louis Seaman, late Surgeon, U. S. V., has an article in which he argues in favor of the restoration of the canteen. Major Seaman has ever been an advocate of the canteen, and his remarks on the subject have been more than once commented upon in the Medical Record. The first and most potent argument in support of the canteen is that the majority of military surgeons who have served in the field, and who are therefore conversant with the needs of the soldier, are of the opinion that the abolition of the canteen was a grave error of judgment. Major Seaman's object in writing his article is to present some of the reasons upon which this verdict is based.

In the first instance it is pointed out that the name "canteen" is a misnomer, and that had it been called the Soldier's Club, or Post Exchange, from the beginning, it never would have been abolished by act of Congress. The purposes of the Post Exchange or Canteen combined the features of a reading and recreation room, a coöperative store, and a restaurant.

After tracing the origin and development of the canteen, the writer gives some statistics: "During the decade of 1878–1887 the number of admissions to the military hospitals for alcoholism and its results amounted to 1,640. From 1888 to 1897, when the canteens had been instituted throughout the army, the number was reduced to 923, or over 40 per cent. In one post, Willett's Point, the admission from this cause in 1889 was 223 for every thousand troops. Two years after the establishment of the canteen, it fell to seventy for one thousand." Captain E. L. Munson, Surgeon U. S. A., reports that: "At Fort Spokane, the amount of sickness resulting directly or indirectly from intoxicants diminished 50 per cent. during the first six months following the introduction of the canteen." Again Captain Munson, in his report on file in the office of the Adjutant-General, states that: "During the seven years of the existence of the canteen the reduction of insanity in the army amounted to 31.7 per cent."

Major Seaman concludes his article as follows: "The Post Exchange, as it existed in 1900, was the most rational compromise that the ripe experience of the ablest officers of the army could devise; it was not abused in the camps; it has been the soldier's friend, often saving him from disgrace and disease worse than death. In abolishing it one might say that Congress in 'killing a mouse, resurrected a monster,' and when considering its restoration, as Congress must, it will do well to remember that the result of its action has not promoted temperance. On the contrary, it has decidedly promoted intemperance, insanity, insubordination, discontent, sullenness, disease, and desertion."

The Association of Military Surgeons of the United States, at their meeting last year, unanimously adopted resolutions recommending the restoration of the canteen, and the American Medical Association and American Public Health Association took the same course. The army canteen was abolished through the well-intentioned, but misguided efforts of certain temperance enthusiasts, principally women, to whom the name of strong drink is accursed, and who had no clear conception of the

true bearings of the case. Now that the abolition of the canteen has not had the results anticipated, why not revert to the system that worked so well.

THE CHARAKA CLUB.

The name of this club will seem as mysterious to most medical men as was the X Club of London, to which interesting reference is made in the "Life and Letters of Huxley." The Charaka Club has ten members and one honorary member, Prof. Wm. Osler of Baltimore. It was organized in this city in November, 1898, by several medical men who wished in some way to get out of the ruts of their daily professional duties, and to interest themselves more particularly in the literary and historical aspects of medicine. That their meetings were of unusual interest is evident from the first volume of the Proceedings,* which has just been published, and which, although it was intended primarily for "its members and their friends," possesses considerable interest for the general medical public. We learn also from the short introductory that "the expectations of the founders have been realized, and incidentally their meetings have been the means of bringing together some literary material, which it was decided to print."

The name of the club was chosen in honor of the sage Charaka, who, as Dr. Sachs shows in his article, is the oldest writer on Hindoo medicine whose work is still extant. Charaka, not Hippocrates, is henceforth to be the ancient of ancients among medical authors. In addition to the subject treated by Dr. Sachs, we note that Dr. Gerster contributes an article on the "Hippocratic Doctrine of Injuries to the Cranium," Dr. Dana writes interestingly of the "Cult of Æsculapius, His Statues and His Temple," Dr. Holden on "Ophthalmology of the Ancient Greeks," while in a lighter vein are Dr. Collins' "Story of the Man Who Wanted to Hypnotize, but not to Pay," and Dr. Dana's amusing collection of all "The Evil Spoken of Physicians." Dr. Peterson has contributed some verses well worth reading.

The club has surely made a good start. Its meetings were serious enough, but there was a happy admixture of humor, wit, and sprightliness. The Charakians are to be congratulated upon the character of the work done and upon the fine appearance of their first volume. We trust that the example of the members of this club will be imitated in other cities, for any movement calculated to lend further interest to the lives of busy medical men should be encouraged; and if, incidentally, as in the case of the Charaka Proceedings, the general medical public can be benefited, there is further cause for congratulation.

DECREASE IN THE BIRTH RATE OF NATIVE-BORN AMERICANS.

That native-born Americans do not produce children as they once did is a melancholy but fully-accepted truth. At the beginning of the last century they were among the most prolific races of the world, but the birth rate of the native-born American has been steadily decreasing, until now the inhabitants of the United States of native stock have smaller families than almost any of the civilized people of the world.

Mr. Weston, writing in a recent number of the *Nineteenth Century and After*, asks the question, "Are the Americans dying out?" and calls attention to the fact that the native born citizens of the United States are ceasing to breed, and that the result of the diminished birth rate is only concealed by the influx of foreign immigrants, who are coming more and more from southern and eastern Europe. The figures supplied in support of this statement are rather startling.

The first generation of Americans after the colonization of New England had families of ten to twelve; the second, third, and fourth generations had families of six and seven, the fifth families of four and five, and the sixth families of three and less. The result is that 275 years after the landing of the Pilgrim Fathers the stronghold of Puritanism is not upheld by the ever-declining American, but by the Irish, German, and French Canadians. If the birth rate had kept up at its earlier rate, and there had been no foreign immigration at all, Mr. Weston computes that there would have been 100,000,000 people in the United States to-day; there are only 76,000,000, even when all the negroes and foreign immigrants are included. Of these 76,000,000, ten and a half millions are foreigners, thirteen and a half millions are born of foreign parents.

Mr. Weston is of the opinion that this process will continue, and that its result will become the more conspicuous by the fact that the foreign immigrants are now coming from Italy, Austro-Hungary, and Russia. Ever since 1881 the rush of immigration to the United States has changed its starting-point from Great Britain and Germany to the above-named countries.

The comparative sterility of native-born American women is a serious matter, but one which has forced itself upon the notice of thinking persons. The woman of this country, whose ancestors were born here, is generally averse to bearing children. She is, as a rule, of fragile make, nervous temperament, and far more intellectual than are women of other nations. But with her growth of brain-power she has declined in physique, and maternity, with her, is an ordeal to be dreaded and avoided if possible. Thus it probably happens that the birth rate among native-born Americans is continually decreasing.

FOOT-AND-MOUTH DISEASE.

As we have before noted in our news columns, an epidemic of this disease has broken out in Massachusetts, especially in the vicinity of Boston. Epizootic aphtha is, of course, not new to this country, although, as it principally affects sheep, it is more common in those lands where these animals are most numerous. The germs of the malady, says a writer in the *Scientific American*, may have been brought over from Scotland fens, or some districts of France, or from some foreign country where the disease is prevalent, on some traveler's clothes who had visited one of these places, and inspected the live stock, or on the straw or hay-packed articles imported from them.

The disease is of germ origin, and is highly contagious. "Persons," states the writer before referred to, "can carry the germs on their clothing or shoes, dogs can transport them, and they can be taken into the systems of a healthy herd which passes over the same road that a sick animal has traversed a few hours previous. Cattle are not the only animals subject to it, for it is contracted by sheep, swine, horses, poultry, and sometimes by man. In the latter it comes from drinking the milk or eating the flesh of infected animals, and sometimes by coming in contact with the sores; for

*The Charaka Club, vol. 1, 1902. Wm. Wood & Co., N. Y.

instance, the hands coming in contact with the teats while milking. The disease has the nature of an eruptive fever, which is easily recognized by the symptoms, consisting of a higher temperature in the mouth, bleeding teats, an erect coat, loss of appetite, and the secretion of 'ropy' saliva. Little blisters about half an inch in diameter, form in the mouth and in various other parts of the body, as on the teats. The animal drivels, and, in walking around, treads on this saliva, in which the virus obtained foothold, when the blisters broke, and gets the sores in his hoofs. The irritation originated by the sores causes the animal to lie down, so that he gets the sores on various other parts of the body. In two or three days the blisters mature, break, and discharge their contents. If a number of these occur in one place, it makes a raw spot and is very irritating. The disease runs its course in ten or fifteen days, and the animal gets well in the majority of cases, although it sometimes proves fatal."

Foot-and-mouth disease seldom infects a member of the human race, and the danger of contracting it by man is so small as to be scarcely worthy of consideration. Yet, at the same time, an epidemic of the nature which is now raging among cattle in Massachusetts and Vermont directly concerns the inhabitants of the surrounding country, insomuch as they are more or less dependent on these herds for the most important articles of food, meat and milk. Thus it is to the interests of the medical profession to learn all that is to be learned with respect to the disease, and to endeavor to devise methods of prevention and of curative treatment.

The Dissemination of Typhoid Fever.

C. E. A. Winslow, instructor in sanitary bacteriology, in the Massachusetts Institute of Technology, writes in the *Atlantic Monthly* for January, on the "War against Disease." Referring to typhoid fever he points out that it is only within the last thirty years that the origin of typhoid fever has been known. Dr. William Budd, in 1873, accomplished more than anyone toward overthrowing the "pythogenic theory" that the typhoid poison was generated spontaneously in the earth or in heaps of decomposing filth. He demonstrated these two essential points, that every case of typhoid fever arises by direct or indirect contact with a previous case of the same disease, and that "the contagious element" by which it is mainly propagated is contained in the specific discharges from the diseased intestine. "The contagious element," or the germ of typhoid fever, enters the body in every case with some article of food or drink contaminated by an earlier victim.

With regard to epidemics of typhoid fever in this country originated by infected oysters, it appears that the possible importance of this article of diet in conveying the disease was first made evident by an outbreak among the students of Wesleyan University at Middletown, Conn., in 1894. The oysters which did the damage in this case were grown in a bed at Fair Haven within three hundred feet of the sewer outlet from a house containing two cases of typhoid fever. They were served at three banquets on the night of October 12. The students present did not live at other times together, and between the three menus there was no common bond not general to the town at large, except the oysters. Two weeks later one in every four of the students who had been at the banquets sickened with the disease. Among twenty-nine guests from other cities, Wesleyan Alumni and members from Yale, who ate the Fair Haven oysters, six additional cases of typhoid fever developed, while four other fraternities which held initiation suppers on the same night, but at which raw oysters from another source were served, had no cases of the disease.

The epidemics of typhoid fever which can be traced to contaminated milk are very numerous, while impure water is the most fruitful cause of typhoid fever known.

Mr. Winslow strongly emphasizes the fact that typhoid fever is a perfectly preventable disease, but that notwithstanding the preventive knowledge possessed by sanitarians, many of the large cities of the United States have not ceased to furnish their citizens with polluted river water containing the germs of this deadly disease. Between 1890 and 1898 there died from typhoid fever an annual average of over 175 persons in Washington, of over 200 persons in Pittsburgh, and over 475 persons in Philadelphia—nearly 8,000 men and women thus perishing of this preventable plague in these three cities during nine years. Commenting upon this state of affairs, Mr. Winslow says: "Allowing for all other possible causes, it is certain that more than half of them were condemned to death solely by the corruption or the incapacity of those municipal officials who permitted the continuance of the existing water supplies."

On the whole, however—owing to the more intelligent modes of treating drinking water and sewage now in vogue in most of the cities of this country—typhoid fever is on the wane, and with increased energy on the part of municipal authorities in insisting that the most modern and effective methods of ensuring a pure water supply shall be enforced, the disease within a reasonable time may become practically extinct.

Association of Brain, Thymus, and Adrenal Defects.

Prof. G. Anton discusses the meaning of the rather frequent association of abnormal developmental conditions of the thymus and adrenals, with similar conditions of the brain, in the *Wiener klinische Wochenschrift* for December 11, 1902: A male, born normally, suffered from frequent epileptic attacks, and died in status epilepticus at twenty-three years. The autopsy showed general, uniform enlargement of the brain (weight 2,055 g.), with slight dilatation of the cavities, and a very capacious and much-thinned skull. Relative to the epileptic attacks, the author says that enlargement of the brain, *per se*, does not involve disturbance of function, as all investigators admit that, with increase of mass, power and function are heightened. The explanation of the convulsions, then, lies in the disproportion between brain development and skull development, which involves increased intracranial pressure. Yet, as Naunyn and others have showed by numerous experiments, even this does not cause convulsions or coma if the blood pressure is simultaneously and proportionately increased. But here the adrenal disease and the precocious degeneration of the heart muscle operated to bring about the necessary disproportion between the intracranial and blood pressures. The coincidence of abnormal persistence of the thymus with hypertrophy of the brain was noted by the older pathologists (Rokitansky, *et al.*). This coincidence is very difficult of explanation. But the persistence of the thymus in this case is, perhaps, explicable by an existent arterial anomaly. A thyroid trunk, originating from the anterior side of the innominate, gave off in front of the trachea two internal thyroid and two thymus arteries. The

older anatomists (Morgagni, Hewson, Cooper, Meckel) also observed that, with absence or great malformation of the cerebrum, the adrenals are small and defective. Recently Zanders has shown in anencephalics, hemicephalics, and cyclopeans a simultaneous stunting of the adrenals; and others have proved a very close connection between brain and adrenal development. The experiments of Borutan, Biedel, and Reiner show that adrenal (suprarenal) extract produces collateral hyperæmia of the brain by constricting the arteries of the body. Consequently the possibility exists that defective adrenal function in the fœtus may involve coincident injury of the vascular system. Zingerle has shown that, in the earlier phase of fetal life, the neural epithelium represents the formative and most important factor in the development of the central nervous system. But with stunting of the adrenals, with consequent disturbance of the chemism of the fœtus, to what extent is the neural epithelium affected? This is the only case on record of enlargement of the brain associated with cystic adrenal disease, former cases of adrenal disease having been associated with brain defects, such as anencephaly, cyclopeanism, encephalocele, etc. A bibliography, and a table of excessive brain weights, from 2,850 grams down, are given.

Treatment of the Nervous Phenomena in Chronic Nephritis.

Dr. James M. Anders, LL.D., Philadelphia, published in the *Therapeutic Gazette*, November, 1902, an interesting article on the above subject. After stating that the treatment of existing nervous symptoms is purely symptomatic, the writer proceeds to discuss the treatment of acute uræmia with convulsions and unconsciousness. In order to obtain free action of the sweat glands, the hot pack is indicated, supplemented by the hypodermic use of one-fourth grain of pilocarpine. Strychnine and digitalis to guard the heart, while if diuretics fail, wet and dry cups should be applied to the loins. If these measures do not promptly restore consciousness, resort should be had to blood-letting from an arm-vein. Dr. Ander's axiom in a case of obstinate uræmic convulsions is, "when in doubt bleed." After which heart stimulants should be administered, reinforced by the injection of the normal salt solution, given intravenously. As to the administration of morphine, Dr. Anders thinks that it is less harmful in its effects in acute nephritis than in chronic, and even then should not be given until other measures, including jaborandi and venesection, have failed, or are contraindicated by great enfeeblement of the circulation. Chloroform by inhalation, he holds, is a capital remedy in the convulsions of uræmia, but must be subordinated to free bleeding. Indeed the author regards venesection as the "sheet-anchor" in cases of uræmic convulsions.

Apoplexy is to be treated as under other circumstances. When a hypnotic is needed Dr. Anders gives the preference to sulfonal, trional, and chloralose. For headache, restriction and regulation of diet, and for the pain phenacetin combined with caffeine.

The distinctive feature of the paper referred to is its writer's vigorous advocacy of venesection in uræmic convulsions. Dangerous cases call for heroic remedies, and upon this fact Dr. Anders bases his treatment. There is no doubt that uræmic convulsions, unless arrested, will soon produce an exhausted condition of the tissues, and fatal results will supervene. In such cases blood-letting can do little harm and may do much good.

News of the Week.

The Plague.—The conference of the various State boards of health, held last week in Washington under the presidency of Surgeon-General Wyman of the Public Health and Marine Hospital Service, adopted a resolution declaring that the presence of the plague in San Francisco has been established beyond a doubt. The conference further declared: "The present danger to California and to the United States lies primarily in the persistence during nearly three years of a definite nidus of plague infection in that part of San Francisco known as Chinatown, but the gravity of this circumstance is greatly increased by the gross neglect of official duty by the State Board of Health of California and the obstructive influence of the recent governor of California, by the failure of the city government of San Francisco to support its city Board of Health, and by the obstacles opposed to the operations of the United States public health service. This conference will consider the safety of the country sufficiently assured as soon as satisfied that a competent city Board of Health of San Francisco and a competent State Board of Health, in co-operation with the United States public health service, will proceed under definite, harmonious, and effective laws and ordinances; that they are provided with ample funds, and that they are jointly and severally in the free exercise of their lawful powers." The conference also adopted a resolution expressing its conviction that it would go far toward the restoration of popular confidence if the United States public health officials were admitted to the same relations with the State Board of Health as have been steadily maintained with the city Board of Health of San Francisco, which body it warmly commended. Ecuador has closed her ports to ships from San Francisco and other Pacific coast countries are contemplating similar action. The foolishness of the suppression policy of the San Francisco authorities must be now most apparent even to its former most strenuous upholders. There is danger now that a panicky feeling will be aroused in other parts of the country, and that the business interests of California will suffer far more than they would have, had the authorities openly admitted from the first the presence of the plague and taken measures to suppress it.

The Increase of Pneumonia.—In an address on the increase of pneumonia delivered before the Michigan State Board of Health, Dr. Reynolds, Commissioner of Health of Chicago, showed by data compiled from the volumes of vital statistics of the federal census for the years 1880, 1890, and 1900 that, while pulmonary tuberculosis (consumption) had decreased from 18.21 per 10,000 of population in 1880 to 14.44 in 1900, pneumonia had increased from 12.56 in 1880 to 13.49 in 1900. These figures are for the whole country, and show a decrease of 20.7 per cent. of deaths from consumption and an increase of 7.4 per cent. of deaths from pneumonia during the twenty years.

International Exposition of Hygiene at Buenos Aires.—The State Department has received from the legation of the Argentine Republic, Washington, notice of the International Exposition of Hygiene to be held at Buenos Aires in connection with the second Latin-American Medical Congress, which will meet in April, 1904. An invitation is extended to public and private institutions interested in the subject to participate in the exposition. Reduced rates for the transportation of exhibits have already been obtained from several steamship companies.

A Method of Resuscitation of the Apparently Dead.—Dr. George W. Crile reports in the *Cleveland Medical Journal* that, by the combined use of intravenous infusions of adrenalin, artificial respiration, and rhythmic pressure upon the thorax over the heart, animals apparently dead as long as fifteen minutes were restored to life. Animals which had been decapitated, Dr. Crile says, were made to live ten and one-half hours.

Treatment of Leprosy.—Dr. John M. Swan of Canton, China, writing of the treatment of leprosy practised by Dr. Adolph Razlag, commented upon in the MEDICAL RECORD of October 4, 1902, says that good effects were noticeable as early as six months after the inception of the treatment. Dr. Razlag has continued his work in this direction during the past few months with noteworthy results.

Physicians in Ecuador.—In a report recently published, the late Consul-General Thos. Nast of Gayaquil, writes: "As numerous letters are received from parties desirous of practising medicine in this country, asking if they will be allowed to practise without passing an examination in Spanish, I wish to say that the law of this country requires all medical men arriving in the Republic to pass an examination before the Medical Board in Spanish before permission is granted them to practise. I may add that there are so many doctors here that unless the physician is a specialist his chances of obtaining much practice are very doubtful; the market is overcrowded."

Mortality in Paraguay.—According to the official statistics, recently published in Paraguay, there were, in the year 1901, 9,000 deaths in that country in a civilized population of 635,571, giving a death rate of about fifteen per thousand.

The Presbyterian Hospital of Philadelphia has received a gift of $30,000 from an anonymous donor for the purpose of building a new maternity house. According to the annual report, 2,500 persons received treatment in the wards of the hospital during the year and 6,000 in the dispensaries.

The Pathological Society of Philadelphia.—At a stated meeting, held January 22, Dr. S. Weir Mitchell read a paper entitled "The History of the Investigation of Snake-venom;" Dr. Joseph McFarland a paper entitled "Venene and Antivenene;" Dr. Hidayo Noguchi one on "The Blood-reactions of Serpent-venom," and Dr. Simon Flexner one on "The Effect of Serpent-venom on the Blood."

Philadelphia County Medical Society.—At a business meeting, held January 21, the following officers were elected for the ensuing year: *President*, Dr. Francis M. Perkins; *First Vice-President*, Dr. J. Cardeen Cooper; *Second Vice-President*, Dr. Wm. S. Higbee; *Secretary* Dr. Wm. S. Wray; *Assistant Secretary*, Dr. Ross H. Skillern; *Treasurer*, Dr. Collier L. Bower; *Censor*, Dr. Wm. M. Welch. Delegates to the Medical Society of the State of Pennsylvania and sixteen new members also were elected, and the reports of directors, treasurer, censors, and Publication Committee were presented.

Fire in the Boston City Hospital.—A fire broke out in the Boston City Hospital during the night of January 22–23, and caused considerable alarm to the patients. A number of men in the delirium of typhoid fever, and otherwise helpless through disease, were removed to a place of safety, while the other patients were quieted until the fire, which was confined to the ward in which it originated, was extinguished. The loss from fire and water was about $5,000.

Gifts to a Medical Library.—Mr. Andrew Carnegie, in searching for new libraries to found or assist, has at last come upon medical libraries. He has offered to the College of Physicians in this city $50,000 for the maintenance of its library, conditioned upon the college raising $50,000 more. Of this second $50,000, F. W. Vanderbilt has given $10,000 and Clement A. Griscom, $5,000.

An Orange Black List.—The Practitioners' Society of the Oranges, which is composed of physicians practising in the Orange villages in New Jersey, has prepared a "black list" of people who will not pay their bills for medical service. The names of the worthy poor who cannot pay for medical treatment are not on the list.

Dr. Adolph Lorenz has arrived in Vienna, after tarrying for a while in Liverpool and London and demonstrating the "bloodless" treatment of congenital dislocation of the hip to such English surgeons as cared to attend his clinics. There was no triumphal progress there, however, and his reception did not even border on the hysterical. In an interview with a correspondent of the Associated Press, after his return home, Dr. Lorenz commented on his cool treatment in England, which he modestly attributed to a lack of enterprise in the British. "American physicians represent progressiveness," he said, "while English physicians are extremely conservative. In America it was difficult to accommodate the doctors and students who desired to attend my clinics, while during my week in London many of the most eminent surgeons showed no interest in the new methods, and others who were present declared the old way to be best."

Grape-juice and the Typhoid Bacillus.—In a recent weekly report of the Chicago Board of Health, it is stated that a study of the action of fruit juices upon the typhoid bacillus has brought out the interesting fact that, while lime-juice, apple-juice, and the juice of the grape-fruit all had a more or less inhibiting effect on the growth or vitality of these bacilli, bottled grape-juice gave the most conclusive results. Cultures of the typhoid and the colon bacilli were used to infect both distilled water and water from the laboratory tap, in a strength of about 10,000,000 bacilli to a cubic centimeter. Bottled grape-juice was then added in proportions varying from 1 to 5 per cent. Examinations made at one-minute intervals showed that some brands had killed the germs at the end of the first minute, the effect being almost instantaneous. The advantage of bottled grape-juice, it is said, is that the quantity required—1 per cent.—does not affect the flavor of the water or disturb digestion, as lemon-juice does with some individuals. The freshly extracted juice of the grape prepared in the laboratory had no effect on the bacilli, even in a proportion as high as 100 per cent.

Medical Reciprocity in Michigan.—The Governor of Michigan has the following to say concerning amendments to the State medical practice laws, in his annual message of this year: "The State Board of Registration in Medicine favors amendment to the medical law, having in view both the elevation of the standard and the uniformity of the act in connection with medical laws of States which have taken an advanced position, in order that worthy and well-qualified physicians and surgeons who have been legally authorized to practise under the laws of other States may be given the right to practise in this State without being forced to submit to a repetition of the examination which they have previously undergone. In order that

Michigan may be able to take advantage of the proposed reciprocal relations, it will be necessary to raise the standard of medical requirements of this State to that of the States willing to enter into reciprocity. These suggestions should have your further careful consideration."

The "Practitioner."—Dr. Malcolm Morris, for eight years editor of the *Practitioner* of London, has retired from the management of the journal and has been succeeded by Dr. W. Cecil Bosanquet. The journal has been slightly altered in shape and a uniform type has been adopted. For the chatty comments on men and things, medico-political and medicosocial, under the heading of "The Month," the new editor has substituted observations on purely medical and scientific topics, entitled "Notes by the Way." The character of the journal is otherwise unchanged.

Mount Sinai Hospital Alumni Association.—The sixth annual reunion and dinner of the Associated Alumni of Mount Sinai Hospital was held at the Arena on January 15. Dr. Samuel M. Brickner presiding. Interesting addresses were made by Mr. Isaac Stern, Vice-President of the Hospital, and Drs. Emil Gruening, F. P. Foster, Mark Blumenthal, William F. Fluhrer, B. Sachs, Nathan E. Brill, Percy Fridenberg, and Walter M. Brickner. The following officers were elected for the ensuing year: *President*, Edward Fridenberg; *Vice-President*, George L. Brodhead; *Secretary*, Charles Goodman; and *Treasurer*, Eugene H. Eising.

Lectures on the Neuroses and Psychoses of Spirit and Drug Addictions.—Dr. T. D. Crothers of Hartford, Conn., will deliver a course of lectures on alcoholism, morphinism, and other drug manias, at the New York School of Clinical Medicine, 328 West Forty-second Street, on the first Tuesday of every month, at 11 A.M. and 8 P.M. Members of the medical profession are cordially invited to attend.

Obituary Notes.—Dr. Margaret Stanton, formerly president of the Onondaga County Medical Society, died at her home in Syracuse on January 22 at the age of fifty-eight years. She was a member of the staff of St. Joseph's Hospital, and was the first woman to receive appointment as a city physician and the only woman to hold the office of president of the Onondaga County Medical Society. She was graduated from the College of Medicine, Syracuse University, in 1876.

Dr. Joseph Edwin Clark, who had been in practice in Brooklyn for over fifty years, died January 19 of pneumonia at St. Peter's Hospital, in his eightieth year. He was graduated from the College of Physicians and Surgeons of New York in 1849. He had been a visiting physician of St. Peter's Hospital since 1875.

Dr. Christopher Kiersted died at his home in Jersey City on January 23, from gastritis. He was born in New York in 1822, and he traced his ancestry back to Hans Kiersted, said to be the first surgeon to settle in New Amsterdam. He had practised in the Greenville section of Jersey City for half a century.

Dr. Max Schede, professor of surgery at the University of Bonn and director of the surgical clinic there, died on December 31. He was born in 1844 in Westphalia, and took his degree of M.D. at Halle in 1866. He was privat-docent at the University of Halle until 1875, and then went to Berlin, where he was chief surgeon to the municipal hospital of Friedrichshain. In 1880 he went to Hamburg as chief surgeon to the General Hospital in that city, and remained there until 1895, when he was called to the chair of surgery at Bonn.

Dr. Charles H. Haeseler died at his home in Pottsville, Pa., on January 22, at the age of seventy-three years. He had been ill for some time with diabetes mellitus. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1853.

Dr. John M. Broomall Ward, deputy physician at the Pennsylvania State quarantine station at Marcus Hook, was killed while boarding an incoming steamer. He was a graduate of the Jefferson Medical College in 1891.

Dr. C. Everett Watson, a homœopathic physician of Conneaut, Ohio, died of tuberculosis at Phoenix, Ariz., on January 18. He was a graduate of the Cleveland Homœopathic Medical College in 1898.

Some Recent Work on the Condition of the Deep Reflexes and Other Symptoms in Transverse Lesions of the Cord.—W. B. Warrington says that the consideration of a number of cases affords warrant for the belief that, while in general the symptom group described by Bastian follows complete transverse lesions of the cord, yet when the disease is of a slowly-progressive nature, the reflex functions of the cord may be retained and the muscular tone be unimpaired, and also that, in some cases, very severe symptoms, approximating to those generally found after complete transverse lesions, may be present, and yet the anatomical lesion be slight or incomplete. This is especially observed in compression of the cord, and indicates that physiological loss of function may be produced without marked anatomical change. From the point of view of surgical interference, it is important to notice that no case of incomplete division of the cord has been recorded in which all the symptoms described by Bastian were present, and in which the lumbar enlargement was intact.—*Medical Chronicle.*

Lateral Section through the Os Pubis.—Gigli considers the reasons which make symphyseotomy, though apparently so simple, an operation second to none in danger and possibilities of serious consequences. An analysis of the conditions under which it is performed shows that it does not conform to the requirements of modern surgery, which demand that, when one of the larger joints is invaded, it shall be under conditions of the most perfect asepsis, and that subsequent complete immobilization shall be practicable. Neither of these is possible in symphyseotomy, in which the uncertain developments of the puerperium must be taken into account, and immobilizing apparatus cannot be applied. The operation is, therefore, surgically considered a mistake, while the substitute he offers has all of its advantages and is technically a correct procedure. This consists in a lateral section through the bone itself, by means of the wire saw to which his name is attached. The operation is free from the embarrassments due to unexpected hemorrhage, ossification of the symphysis, etc., which may occur during symphyseotomy, and, in addition to the ordinary instruments, requires only a ligature carrier and Gigli saw. An incision is made from the mid-line down and outward toward the labium majus to the lower end of the os pubis, where the subpubic tubercle is felt. This incision is carried boldly down to the bone, as no vessels are encountered. Through the upper angle of the wound the ligature-carrier is brought behind the bone and then, under the guidance of the fingers of the other hand in the vagina, is pushed down and out through the lower angle. A ligature of silk is then drawn up behind the bone, and to this a saw is attached and then drawn up into position to cut through the bone. The venous oozing is slight and easily checked by compression, while the clitoris, urethra, and the vesical and vaginal plexuses are wholly out of danger.—*Centralblatt für Gynäkologie.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

NEW YEAR—PREVALENCE OF SMALLPOX—LEAGUE OF MERCY—THE NEW WATER BOARD FOR LONDON—FREE ALCOHOL FOR RESEARCH—NEW INEBRIATES' ACT—REPORT OF INSPECTOR OF RETREATS—CASES OF INEBRIETY—DURBAR HONORS—KING'S PRIZE ESSAYS—HOSPITAL FUNDS—RATING THEM—ELECTROTHERAPEUTIC SOCIETY—PROPOSAL FOR A NATIONAL INSTITUTION—PAYING HOSPITALS AND PAY WARDS—OYSTERS—PROFESSORSHIP OF TROPICAL MEDICINE—THE UNIVERSITY SEAT—EPIDEMICS.

LONDON, January 10, 1903.

THE Christmas recess passed and the new year begun, teachers and students are again at work in the schools looking forward to the latter half of the winter session as a period of strenuous endeavor.

Smallpox is spreading in several provincial towns. In almost every case it has been introduced by tramps. More than one such source has been traced at Birmingham. The outbreak at Stockport is more serious; seven deaths have occurred, and fifty-five patients are under treatment, nearly all of them tramps or occupants of common lodging-houses. Sheffield has had some thirty cases introduced in the same way, and other northern towns are being invaded. The local authorities are recognizing the great danger of a vagrant population and increasing their vigilance.

The Liverpool epidemic is increasing. This week the M. O. H. reported 205 cases under treatment in the City Hospital. The new cases during the week numbered seventy-four against fifty-six in the previous week. One death had occurred.

The League of Mercy has been making its way quietly, and has already collected a considerable sum for the hospitals. Eight thousand pounds has been handed to the King's Hospital Fund for this year, an advance of £1,000 over the amount for 1901.

The money collected by the League is largely composed of annual subscriptions of one shilling. This exactly meets the intention of the King in founding the league about three years ago—to establish a machinery to render it possible for humble people to contribute to the hospitals. These persons seem to have recognized that as their money goes to the hospitals without any deduction for expenses, their small sums are of service.

The Local Government Board has issued the necessary order, under the new act, for constituting a metropolitan water board to take over and carry on the undertakings of the several water companies. The ratepayers seem to have been surprised at the bill having been rushed through, and not a few are giving expression to fears of a great increase in the costs. On the other hand, some argue that to get rid of the companies is a benefit at any price.

The Board of Inland Revenue have at last granted a concession that has long been urged, viz., a remission of the heavy duty on alcohol used in scientific laboratories.

A new licensing act came into force yesterday. It is chiefly directed to the punishment of persons found drunk in public places, and represents the modicum of legislation promised by the government as their contribution to temperance reforms. The publicans are much incensed at some of its provisions.

In connection with this subject, I may mention the report of the inspector under the Inebriates' Acts (Dr. R. W. Branthwaite) for 1901, which has just appeared as a Blue Book. There are now twenty-one licensed retreats, this being the largest number that has been attained during the ten years the acts have been in force. But the growth of these establishments, if slow, has been progressive. Ten years ago there were ten retreats conducted as purely philanthropic concerns. Now there are twelve. These institutions tend to prevent those conducted on commercial lines from becoming too exclusive, and so provide for the treatment of patients at low rates of payment. But there seems to be no provision for destitute cases. One great difficulty of dealing with confirmed inebriates is that, after all, their entrance into these institutions must be voluntary. Nothing short of compulsion can meet such cases, and the Legislature could not be induced to forfeit the freedom of anyone for a term sufficient to be of any curative or preventive value.

With regard to cures, Dr. Branthwaite thinks that inebriates are seldom cured in the strict sense—that is, brought back to a state in which they can safely take alcohol, even in strictest moderation. Nothing short of absolute abstinence will preserve the patient from relapse. But he knows many who have been so far weaned from drink as to live happily without it, so long as they do not touch it.

As to the percentage of good results, Dr. Branthwaite admits the impossibility of supplying satisfactory figures, for they should be collected, not at the time of leaving the retreats, but a year or more later. Nevertheless, he is confident that much good is effected, and taking all cases, without selection, as they apply for admission, he estimates that good results occur in from 25 to 30 per cent. Compared with any other mode of dealing with inebriates, he is sure that this system is incomparably superior. His wide experience as inspector under the acts is entitled to most serious consideration. So valuable does he consider enforced abstinence, that he thinks there might be a place for retreats which took patients for short periods, though the numbers of such persons relapsing would be greater than in cases of long detention.

There is one other point I should like to mention, viz., that Dr. Branthwaite repudiates the pessimistic assertions that have been so freely made as to women inebriates. One has so often heard persons of no special experience declare that it is hopeless to attempt to reform a female drunkard, that it is very refreshing to find Dr. Branthwaite expressing the conviction that women are quite as likely to reform as men—possibly more so. He has known some who have been teetotalers for ten years, never once breaking down in that time.

The New Year's honors list was exclusively an Indian one, and intended to mark the great ceremonial at Delhi. Several Indian medical officers received promotion in their orders, or the first step, according to the length and distinction of their services.

The first prize essay for the King's Sanatorium for Consumptives appears in book form to-day. The *Lancet* issued to-day includes all three essays in unabridged form. So I refrain from remarks on them. They almost, if not quite, fill your contemporary's pages, and make it a heavier number than ever.

LONDON, January 17, 1903.

THE Council of the Metropolitan Hospital Sunday Fund met on Tuesday. The Lord Mayor said a special meeting would be held at the Mansion House on June 8 to further the object of the fund. An attempt is then to be made to interest the provinces in the work. It was stated that no less than 60 per cent. of the patients relieved in our metropolitan hospitals come from country districts, which contribute nothing to the fund. The secretary said he had written to the incumbents of about 700 country churches, but they seemed slow to respond.

The report of the Saturday Fund, which is doing equally good work, shows that it collected last year £17,165, as against £16,754 in the previous year. The accounts will be kept open until Monday next, by which time it is hoped another £3,000 or more may come in.

The rating of hospitals has long been a sore subject, and is once more coming to the front. The report of a select committee of the House of Commons in July, 1900, recommended that hospitals and infirmaries should be exempted from rates. But nothing has been done, and the recommendation remains a mere pious opinion.

You know we have an Electrotherapeutic Society here. It has not attracted much attention at present, but then it is very young, a mere infant, so to say. The society only lately celebrated its first anniversary, on which occasion Mr. Edmund Owen responded to an invitation to deliver an address. Mr. Owen has a forcible way of expressing his opinions, and did justice to himself and his subject. He congratulated the members on having established the society, and stated his conviction that the step was a necessary one. He advised them, at any rate for a time, not to have reports of their work in the weekly journals, but to have their communications recorded in their own annual. He warned them, too, of the necessity of being very careful that all papers accepted were sound and honest; for every now and then persons would probably come to them begging to show certain apparatus, or even to read papers, which would be discovered later to savor of rank advertisement. If there are two secretaries, he said, one might be gentle, but the other must be firm; if one is Mr. Spenlow, the other should be Mr. Jorkins; if one is positive, the other should be negative.

Mr. Owen proceeded to expose some of the camp-followers of the profession who have fastened on electricity as the most promising field for their extortions from suffering and credulous humanity. He specially exposed the pretences of certain institutions which have been run by unprincipled and unqualified persons, and are the homes of every kind of quackery and imposture. But he did not stop here—he did not hesitate to give a faithful picture of the position of the ordinary practitioner in respect to electricity and to utter a strong condemnation of those, who, ignorant of the right use of this agent, instead of recommending their patients to a consultation with

experts, actually encouraged them to resort to these quack establishments.

But Mr. Owen was not content with destructive criticism. He sketched a plan for meeting the needs of the case, and it is this constructive part of his address which most attracts me. Seeing the costliness of the apparatus required for efficient electrical treatment, which renders it impossible for the young physician to invest in a full plant, and, moreover, the fact that if he could, he would not have house room for it, he suggested that the society might secure premises and establish an institution in which every kind of apparatus connected with electrical therapeutics, with *x*-ray and light work, and allied methods, should be found, and where members could use them themselves, or send patients to be treated by others, who devoted themselves to research and to carrying out the most difficult and time-consuming therapy. The scheme, if ambitious, he believed could be realized under the Limited Liability Acts, and in a year or two every practitioner in the Empire would know of the existence of the institution, and would be glad for patients to be treated there by those who were acquainted with the most advanced science of electricity, and understood how it might best be employed as a remedial agent.

If any one should be shocked at the notion of a limited company, it may be said that the British Medical Association is registered under the Acts, but Mr. Owen does not propose the addition of his great institution to the charities of London. He would have it not merely self-supporting, but returning fair dividends. He would not play into the hands of the bogus promoter, who knows quite well the quixotic ideas which make doctors an easy prey. He holds that good work deserves good pay, and reminded his audience that in every other profession the laborer is considered worthy of his hire.

This question of pay has been brought before the public again by the reopening, after extensive alterations, of the Fitzroy Home-hospital, which was established by an association for providing accommodations for paying patients. The intention was to give well-to-do patients all the advantages of a hospital for adequate payment. The fees range from four to ten guineas, and as the patients have also their own doctors to attend them, it is obvious that they must be fairly "well-to-do" to afford to enter. At the reopening, yesterday, it was stated that, since 1880, no less than 5,376 persons have been treated in this institution, the number of medical men who have attended them being 1,476. An appeal was made to the public for funds to pay for the rebuilding, £10,000. Yet one would suppose that, at the fees charged, the profits should have sufficed, and it may be doubted whether those who could afford those fees should have a hospital provided for them by what is very like charity.

But a still larger question as to pay was introduced by Sir H. Burdett. He sees that there is need for such an institution on a more economical scale, so as to be available for patients who could not afford more than thirty shillings or two pounds weekly. To meet their cases he wants all the hospitals to set apart "paying wards," or, rather, he would have them erect separate buildings on their grounds for this purpose, and he estimated that half a million sterling would suffice. This is a large order, and opens various questions. There cannot be a need for so many paying hospitals as those for the really poor. Is there any reason why paying institutions should be administered by the managers of free hospitals? Every general practitioner will say no. These managers have encouraged the abuse of hospitals, and should not be permitted to extend their work. They have already plenty to employ them, and paying hospitals should be run on altogether different lines.

Sir J. Crichton-Browne delivered an address on Saturday to the Sanitary Inspectors' Association, of which he is president, in which he referred to the epidemic of typhoid fever due to contaminated oysters. Emsworth, he said, in proportion to its size, had suffered from a severe epidemic through the copious specific poison poured into the oyster-beds, where it floated to and fro until the oysters had supped their fill. Then, when well charged, they were packed and distributed, to carry havoc where they were sent.

Among the letters to the daily papers provoked by the outbreak I notice a particularly foolish, not to say dangerous, one, which declares that, by keeping oysters a few days in fresh water and oatmeal, the bacillus is removed. The fresh water tends rather to produce disease in the mollusc, and oatmeal is not a food for it. The bacillus will live a long time in the tissues of the oyster.

It was announced, at a meeting of the Liverpool School of Tropical Medicine, that £10,000 had been collected or promised for the endowment of a chair in the University College of Liverpool to be called the "Sir Alfred Jones Professorship of Tropical Medicine." Major Ronald Ross has been elected the first professor, and the meeting tendered him their congratulations on his successful connection with the Nobel prize.

Sir M. Foster, being unable to make up his mind whether to retire from the representation of the University, has asked his constituents to do it for him. So a circular is going round to those who voted for him before asking them their opinion.

The Medical Directory for 1903 begins a new series of a somewhat more convenient shape. The summary shows the total number on the register to be 37,291, of whom 6,309 are in London, and 16,422 in the English provinces. The growth of London is a standing wonder to many of its citizens, but the increase in the number of practitioners seems still more remarkable to our senior colleagues.

A three-masted vessel has arrived at Dunkirk from Saigon, on which three deaths from beriberi had occurred during the voyage, and several sailors had to be removed to the Dunkirk hospital.

Smallpox continues to spread in the northern towns. Up to Saturday eighty-eight cases had been notified in Bolton, and the adjoining towns of Radcliffe and Farnworth, sixty-six having occurred in Bolton alone, one a clerk employed in the Town Hall.

At Chesterfield three admissions and one death were reported at the isolation hospital. One was in the workhouse. Another, more significant, at the local iron works, and he had been associating with others for several days before calling on a doctor.

The scourge is also at Chester, Crewe, Nantwich, and Shrewsbury. At Sunderland the captain of a vessel undergoing repairs was removed to the isolation hospital.

OUR PARIS LETTER

(From Our Special Correspondent.)

PRIVATE TUITION FOR MEDICAL INSTRUCTION IN PARIS—ABSINTHISM IN FRANCE—THE TREATMENT OF APPENDICITIS—INCREASE IN THE POPULATION OF FRANCE—BETTER METHODS OF MEDICAL INSTRUCTION—BACTERIA IN THE URINE OF CONSUMPTIVES—PRECAUTIONS TAKEN IN ODESSA AGAINST THE SPREAD OF BUBONIC PLAGUE.

PARIS, December 26, 1902.

THE practice of having private tuition for medical instruction is increasing daily in Paris. In former days, for instance, the preparation for the examinations of the internate, the hardest in the medical career, was made under the direction of three or four internes, who were willing to give their services gratis. This is being changed, and special courses are given, for which a specified amount must be paid. By obliging students to pay tuition fees, their number can be reduced, and the instruction is much more thorough. At Professor Pozzi's clinic, at the Hospital Broca, a series of courses in gynecology is given, and only twelve students are allowed at each course. The subjects treated are of practical value, and are as follows: How to ask questions of a patient; the ovarian function; gynecological examination; abdominal examination; interrogation of a patient by the students; examination of the same; vaginal and uterine dressing; diet tables in gynecology. Other courses on surgical operations in gynecology, on the treatment by physical agents, and on bacteriology and pathology, as applied to gynecology, will also take place in Pozzi's clinic.

The question of alcoholism in France is getting to be more and more important, and any law which is destined to check the amount of alcohol sold to the public is apt to be shelved, as a large part of the State revenue is due to the taxes on distilled liquors. Whereas only 600,000 hectoliters of alcohol were drunk in 1850, the amount that is taxed at present is about 2,000,000 hectoliters. The most sinister sign is the amount of absinthe consumed: In 1885, only 57,732 hectoliters; in 1896, 182,585, and in 1900, 238,477 hectoliters, which shows that the consumption of this poison has quadrupled in fifteen years. Then there is a large amount of alcohol distilled by what are called the "bouilleurs de cru," or private distillers, who are allowed to distil their own produce.

During the month of November the Society of Surgery was the theater of a long and varied discussion on the treatment of appendicitis, the most different opinions being brought forward. Dr. Routier, who is a surgeon of the Necker Hospital, began the discussion by stating the reasons why he always operated as soon as possible. He said he had never regretted operating too soon, but he had sometimes had cause to regret that he had deferred the operation. His statistics are as follows: Operations *à froid*, 49 cases, 49 cures: acute appendicitis, 17 cases with 17 cures; acute appendicitis with abscess, 19 cases, with 17 cures and 2 deaths; appendicitis with peritonitis, 6 cases, 3 cures and 3 deaths. Dr. Gerard Marchand, surgeon of the Boucicault Hospital, described the case of a

child seven years old, whom he did not operate, as the symptoms were so quickly modified that he was led to think he had made an error of diagnosis. A few days afterward, Dr. Marchand being away, Dr. Brun was called, and found the child so low that he refused to operate. Dr. Quénu, one of the best French surgeons, said he thought it was hardly possible in many cases to be absolutely sure of the diagnosis of appendicitis, and wondered whether so important an operation as laparotomy could be advocated in such cases. He felt that during the first two days absolute rest and abstinence should be enforced, and if there were the slightest suspicion of a change, then the operation should be carried out. Professor Reclus's opinion is that an operation should be carried out immediately when the surgeon is called at the very start of a clear case of appendicitis. Otherwise, if called later, when the symptoms are of average intensity, he considers it best to let the reaction die out. Dr. Nélaton, the son of the celebrated Nélaton, the surgeon of the Emperor, remarked that no special formula could be applied to all cases. Two symptoms are of special importance: the alteration of the face, and, on the other hand, the acuteness and long duration of the pain, which require an immediate operation. Dr. Tuffier insisted on the frequency with which patients suffering from appendicitis effect a cure spontaneously, and he remarked that generally those who had had a fairly severe attack were apt to remain free for a longer space of time from any recurrence. Dr. Tuffier believes in operating all cases of appendicitis when seen in the first thirty-six hours, unless there is some doubt as to the diagnosis. During the course of an appendicitis Dr. Tuffier is an opportunist. As for operating after the attack is over, Dr. Tuffier does not consider it well to operate in all cases, but reserves the knife for those who have had slight attacks, as he considers that a severe attack with pronounced local reaction is followed by a permanent cure in many cases. During the last two years Dr. Tuffier has operated 155 times for appendicitis; 83 times *à froid* with 83 cures; 9 in the first thirty-six hours, with 9 cures; 63 during the course of the disease, with five cases of diffuse peritonitis. Dr. Poirier, who has just been chosen professor of anatomy in place of Dr. Farabeuf, always operates all cases of appendicitis immediately, and his death rate is only 8 per cent. He does not carry out any special precausions so as to protect the general peritoneal cavity, and he drains with four large tubes, two near the cæcum, one in the Douglas, and the other before the small intestine. Dr. Ricard holds about the same opinions as Dr. Quénu. Dr. Walther gave his statistics during the last two years and a half: 203 cases with 8 deaths; operations *à chaud*, 23 cases with 15 cures and 8 deaths; operations *à froid* after severe form, 74 with 74 cures; operations *à froid* after light attack; 106 cases with 106 cures. Dr. Richelot thought that all cases which appeared severe from the start should be operated on immediately. Later, one of the best symptoms is furnished by the appearance of the patient, their being a certain anxious look, which denotes the gravity of the case.

The population of France diminished during the year 1900–1901. The report showed an excess of 25,988 deaths. During the year 1901–1902 there was an increase of the number of births (857,274 instead of 827,297 in the previous year), and a decrease in the number of deaths (784,876 instead of 853,285). This increase in the population is, however, very small, and during the last five years has been much less than during the preceding five years.

Dr. Lavarenne, the chief editor of the most important French medical paper, the *Presse Médicale*, published an article recently on the change that had taken place in the teaching of medicine at the Paris Faculty. Foreigners had almost completely abandoned the French school, but the progress made has tended to bring them back. Courses are now much more practical than they used to be, and the subjects to be treated are indicated in detail. One example will show the difference: On the announcement of the course of therapeutics the following is written up: "The course of therapeutics begun by the professor during the winter session will be finished by the professor agrégé during the summer term and will last eight months."

At a meeting of the Society of Biology, held on the 15th of November, Drs. Fournier and Beaufume described the results they had obtained in examining the urine of tuberculous patients. Fifteen cases were examined, and Koch's bacillus was found each time, and that without there being any special lesion of the kidneys. The urine was, of course, centrifuged, and the coloration was carried out by the usual methods.

It is interesting to note what measures have been carried out at Odessa to prevent the spread of the plague. All owners of houses are obliged, under penalty of 300 roubles' fine, to poison the rats with a culture of the septicæmic microbe, which is fatal to the rats. The latter is sold by the bacteriological institute of Odessa, at 40 cents for half a liter, which is enough to infect two pounds of bread. All old flooring must be taken up, covered with tar, and the slits filled with dry lime.

OUR ALBANY LETTER.

(From Our Special Correspondent.)

THE PROSPECTIVE WORK OF THE STATE LEGISLATURE IN MEDICAL LAWS—THE CORONER QUESTION—THE STATE SOCIETY'S CHARTER AND THE STATE MEDICAL ASSOCIATION.

ALBANY, N. Y., January 27, 1903.

THE present session of the Legislature gives promise of being fruitful in attempts at legislation involving issues of moment to members of the medical profession. Much of that which will be proposed will never live beyond the second reading of bills, some of it will give rise to discussion and debate more or less acrimonious and but little, if any of it, will be enacted into law. Physicians are wont to criticise severely legislative bodies generally, because of their lack of knowledge and dirth of interest in affairs medical, but it is a fact, strange as it will seem to the uninitiated, that the Legislature of the State of New York has rarely, if ever, refused to pass laws involving medical issues when the profession has been united in advocating their desirability. The present medical practice act is a striking instance of the correctness of this statement; for years and years divers bills were presented to the Legislature, all involving improved methods of medical teaching and of medical control by the State, but all failed of passage because medical factions favored their own and fought all other proposed medical laws, but when in 1890 homeopaths, eclectics, and our own, united on salient features agreeable to all, there was no voice raised by member or senator against the mutually approved legislation, and so the law was passed. It would be wise therefore for medical men who contemplate asking legislative aid from the State of New York to make sure that a healthy and practically unanimous sentiment is back of them from among members of the profession. No relegation of the Coroner to "innocuous desuetude," much as a wise change in the management of the investigation of deaths from unknown causes is desirable, will follow from the conniving of a health board here and a district attorney's office there, unless wholesome medical sentiment is back of the proposition; no additional moneys will be contributed by the law-makers "in the name of science" if they be not satisfied that this new phase of paternalism is not an attempt at commercialism and a covert scheme at added political pap for some chronic medical officeholder; no new legislation will come to pass whereby unskilled persons, parading under the banner of a so-called religious sect, may obtain a short cut to medical practice any more than our chosen legislators will enact statutes lowering the standards of medicine and of decency by placing on a par with those who have met the State's high tests, men and women who profess a "pathy," whose only good features are part and parcel of but one of the many branches of medicine and taught wherever a medical degree is honestly sought and decently acquired—neither of these will be encompassed because the medical profession is opposed to them. Educators generally are commencing to recognize the medical man as a factor in the great scheme of human betterment by the mind improved, and all attempts to let down the bars which now keep the ignorant and illiterate from the fold of medicine will be fought as fiercely by them as by the members of the profession, just as the latter would fight any attempt on the part of the politician to divert from its proper channels such moneys as are the part and province of those who control our secondary and higher educational system. The annual session of the Medical Society of the State of New York, like most of its predecessors, was replete with much of scientific worth. The provisional program evidenced a careful attempt to deal with the most recent advance in medicine and surgery, and the list of participants was replete with names which stand high in the medical world. There seems to be a unanimity of opinion among the members against the proposition of the New York State Medical Association which would rob the society of its charter, granted in 1806, and many, who would be willing to concede all else for the sake of harmony, will fight to the last ditch against such a surrender. Again, there are those who under no circumstances will vote for the merger of the two bodies on the lines now proposed. An ex-president of the society in the presence of the writer recently declared himself as follows: "For a score of years we have maintained the position which declared in effect that gentlemen needed no written code in order to comport themselves properly. Slowly but

surely that idea has become the accepted one among the profession throughout the country. Now, when the victory is practically won, an association of physicians, who fought us and our views in all but "Donnybrook fair" fashion, have the temerity to ask us to disband in order that they, whose cause for existence is to this day unknown, excepting to combat and annoy us, may do likewise, and thus start afresh with us, probably to try to lead us in a joint organization. They will never get my vote for such a proposition, and the only man I know who is earnestly for this union, no matter what the basis, is a member of the profession who acts so ridiculously strenuous for harmony as to inspire the thought that he fears he may not live long enough, if harmony comes about naturally, to become President of the American Medical Association."

Progress of Medical Science.

The Boston Medical and Surgical Journal, Jan. 22, 1903.

Vaginal Cœliotomy, Its Scope and Limitations.—J. Riddle Goffe states that the more experience he has in the vaginal operation, the broader becomes the field of application, until it seems to him that any pathological condition that is confined to the true pelvis can be dealt with as satisfactorily, with as permanent results, and with far greater safety to the patient than through the abdominal incision. His cases have embraced every variety of disease from simple retroversion with adhesions to prolapsed and cystic ovaries, unilateral and bilateral salpingitis, ectopic gestation, fibroid tumors of the uterus and dermoid cysts. The method lends itself to every form of conservative work upon the uterus and its appendages that has been suggested in the trend of recent modern gynecology. The successful application of it requires patience, experience and skill, but when once the profession has been convinced of its superiority, it will steadily and rapidly grow in favor and become the accepted method for the man who practises the specialty of gynecology.

The Importance of Careful Examination and Frequent Cultures in Doubtful Throat Cases.—W. P. Coues reports the case of a patient who was seen on January 11, 1902. Three days before, he began to feel slight sore throat, not sufficient to keep him from his work. On inquiry it was learned that he had seen a little child on Christmas Day who subsequently developed diphtheria. The following day, on tipping up the uvula with a throat stick there was seen on its posterior surface a triangular piece of membrane the size of an almond. A culture was taken, and 4,000 units of antitoxin given. A positive report was not obtained until the third culture. The membrane remained confined to the posterior surface of the uvula. There was very slight constitutional disturbance. The patient made a good recovery. The author concludes by quoting from Dr. Fussell: "Always make a culture in throat cases. When called to see a sore throat of doubtful character, give antitoxin at once; give a large dose; 2,000 to 4,000 units have proved sufficient in the writer's experience, but in desperate cases much larger doses may be used."

New York Medical Journal, January 24, 1903.

A Study of the Deaths Occurring in New York City on the Opposites of Twenty Streets During the Year 1895.—This study was undertaken by A. E. Thayer in order to determine if there was any difference in the mortality on the northern sides of the streets as compared with that on the southern. He offers the following conclusions: (1) The mortality on the north side of any street in the district studied is liable to be higher than the mortality on the south side of the same street. (2) The higher northern mortality is due chiefly to three diseases: pneumonia, phthisis, and nephritis. The first two are especially fatal during cold weather, when the proper ventilation of living and sleeping rooms is most likely to be neglected; the third is also affected by lack of air and sunlight, both directly and also indirectly by the depression of mind consequent upon darkness and poor air. (3) On the south side the greater freedom from these causes of death is due chiefly to the advantages of sunlight and ventilation enjoyed. (4) The supply of air and sunlight has more effect upon the health of people living on the south side of a street and less upon the north, owing to the general habit of New Yorkers of living in the rear of the house, *i. e.* in the more sunny and airy rooms upon the south side and in the less sunny and airy upon the north. (5) Zymotic diseases appear to be independent of these conditions, and may occur in excess upon the south side of the street; in such cases the mortality also may be higher on that side. (6) "Rear" houses are situated less favorably than single houses on a lot, because not only are they darker and less ventilated themselves, but they also deprive the other house of its proper light and air. This is applicable to the south side of the street; on the north, the house on the street acts as a "rear" house to the one behind it, by cutting off its light and air. (7) The width of any street and the distance across yards, measured from the back of one house to the back of another, should be as nearly as possible the same, *i. e.* the latter should never be less than the former; and the height of dwelling-houses should bear some relation to these measurements, so that one house may not deprive another of its light and air. (8) In the case of contagious diseases in any family, the importance of keeping the other children from school is closely related to the question of infant mortality below the age of five years. (9) In general, people should be urged to keep their windows open and their shades up as much as possible, and this especially for dwellings on the north side of the streets and during the colder months of the year, when ventilation is most neglected.

Chronic Gastritis and Gastric Motor Insufficiency in Children.—F. L. Wachenheim believes that chronic gastritis is one of the most common diseases between the ages of two and twelve years, and that motor insufficiency is often associated with it either concurrently or secondarily. In the pure gastritis cases the patient is pale and looks underfed, occasionally is fairly stout, but is reported to have lost weight, has a coated tongue, headache, and more or less epigastric pain aggravated by feeding. Constipation is variable, and sleep more or less fitful. Reaction of the stomach contents is feebly acid. Free HCL. is scanty or absent, but some peptones are produced before the deficient gastric secretion is exhausted. Treatment of such cases is comprised in diet, lavage, and medication. Under the latter heading the use of hydrochloric acid and a bitter tonic is given, though the author admits that the practice is largely a useless one as compared with the great advantage of lavage. Cases of motor insufficiency present evidences of gastralgia, varying irregularly, often quite severe at times when the stomach should normally be empty, progressively increasing after the taking of food. Local tenderness is usually present, much more regularly and more marked than in simple gastritis. Second or even first among prominent symptoms should be placed constipation, usually very obstinate, most of all in rachitic cases. Anorexia is sometimes not very noticeable; we are frequently told that while the child is thriving poorly, it is taking abundant nourishment; perversion of the appetite is not so prominent, as it usually is in gastritis. Abundant eructation of gases is characteristic. Objectively the appearance of the child is apt to be rather worse than in even prolonged gastritis; general thinness is contrasted with a prominent abdomen; the facial cast is often suggestive; rachitis, of course, shows its well-known stigmata. In such cases lavage is of value only if there is very prolonged retention of ingesta, say over twelve hours, the best time in such cases being before breakfast, if possible; otherwise more will be accomplished by diet, attention being directed to the giving of small meals at three-hour intervals, the variety of food being adjusted, as far as possible, to the sufficiency of the gastric secretion as established by the chemical tests. Among drugs, nux vomica takes the front rank, acting as a general stimulant to peristalsis; it is well combined with bismuth and sodium bicarbonate to check fermentation, and magnesia to counteract the constipating tendency of these two. Sometimes the constipation dominates the picture and requires the most attention, and in these cases he has found cascara sagrada the most valuable drug. When circumstances permit, massage should be employed; while inapplicable to the *clientèle* of a dispensary, in private practice its value is promptly made evident.

Medical News, January 24, 1903.

Subphrenic Abscess as a Complication of Appendicitis.—Henry A. Christian and Louis C. Lehr have made a study of 4,028 autopsies, in eighty-six of which death was found to be due directly or indirectly to acute appendicitis. Of these eighty-six cases seven, or 8.13 per cent., showed an involvement of the subphrenic region in a purulent process, although, in a strict sense, not each one was a case of subphrenic abscess. The writers then review these cases, and give many interesting data. In these seven cases the affection was unilateral six times—four times on the right, two times on the left. In one case it was bilateral. Right-sided subphrenic abscess is far the more common following appendicitis. Subphrenic abscess secondary to appendicitis may occur in one of four ways: (1) As a localized abscess, a part of a general purulent peritonitis; (2) by extension of the diseased process from the appendix to the subphrenic region by an intraperitoneal route; (3) by extension of the diseased process by an extraperitoneal route, either by way of the lymphatics or by infiltration through the retroperitoneal tissues; (4) by way of the blood current as part of a general embolic process, or as a sequence of liver abscesses which are of

embolic origin by way of the portal vein. The greatest number of cases originate by extension, 2 and 3. Whether the route will be intra- or extraperitoneal depends upon the situation of the appendix and the periappendicular process. If the latter is retrocæcal, and so extraperitoneal, the chances are that the process will take an extraperitoneal route. When the abscess is retrocæcal, it is claimed that there is greater liability to the formation of a subphrenic abscess. In cases of appendicitis the pleura may become involved in an inflammatory process in two ways: (1) By extension from a pneumonic focus or infarct in the lung; (2) by extension from the abdominal cavity, either by way of the lymphatics or by erosion of the diaphragm. This latter form constitutes the appendicular pleurisy of the French writers, is very often associated with subphrenic abscess, as was the case in four of these seven cases, and is almost always right-sided.

Tonsillitis Classified as an Infectious Disease.—Walter Sands Mills declares that all catarrhal diseases of the nose and throat are more or less contagious. He defines an infectious disease as one that can be transmitted from person to person; one in which, in many cases, there is a definite history of exposure, followed by a period of incubation before the onset of symptoms in the new patient; or a disease one or more stages of which may be contagious, and set up a similar train of symptoms in a previously well person. The writer says that his reason for classifying tonsillitis as an infectious disease is based solely on its clinical history. There is no known specific bacillus for tonsillitis. He then reports a series of cases which will show the contagiousness of the disease. One attack predisposes to another. It is often found associated with many of the other infectious diseases. Mills suggests that it be called an acute infectious disease with local manifestations. Every patient with this disease should be isolated at once, put to bed, and placed on a liquid diet. For local treatment a gargle of cheap claret wine is used every two or three hours. At the very onset aconite in small doses, often repeated, is frequently of service, but not in the follicular stage. If there is intense congestion of the throat and high fever, a 1-per-cent. solution of belladonna is the best remedy. In follicular tonsillitis the best remedy is phytolacca. The writer uses drop doses and 1-per-cent. solution every one or two hours. Its action is almost specific. If suppuration has already begun when the case applies for treatment, sulphide of calcium in 1-100 grain doses is the best remedy for clearing it up. The writer, in his experience, has never had a case go on to suppuration.

American Medicine, January 24, 1903.

Transmissibility of Plague.—W. J. Calvert has contributed valuable data to the knowledge of this subject. While in Manila he performed many experiments in order to learn the characteristics of the plague organism. He inoculated sterile slips of writing paper with the bacillus, and found that an animal inoculated with these cultures recovered after two hours and forty-five minutes of exposure on a brick pavement to direct sunlight, developed a fatal attack of plague. The organism seems most susceptible to disinfectants; weak solutions of the several poisons kill the bacilli in a remarkably short time. On media, cultures maintain their virulence for many months. Even in a dried state virulence is long maintained. It is easy to explain the transmission of plague to foreign ports, since it has been proved that the organism can live forty-four days on dry paper and forty-eight days in dry organs. Favorable media are to be found in all of the Oriental cities. Lymphatic glands harbor the first organisms entering the body. Here they multiply and later gain access to all parts of the body. The blood may be infected from the second day of disease until death. Domestic animals are well known to be susceptible. All nationalities are susceptible. Raw material and fabrics may be infected by sputum, etc. Apparent racial immunity is due to some artificial protection arising from certain national characteristics. Of these, dress which best protects the individual, personal, and domestic cleanliness, are most important. Experimentation on animals has shown that an introduction of bacilli into the tissues is sufficient to produce plague. Much discussion has failed to decide the possibility of contracting plague through the digestive tract. Infection through the genitals, though rare, has been noted. Direct transmission plays a minor rôle in the spreading of plague. In indirect transmission the viability and virulence of the organism are of prime importance. In infected cities certain houses become, so to speak, endemic plague centers in which case after case develops in spite of thorough disinfection. The writer sums up this work as follows: It may be said that the plague organism is long lived; is carried by raw materials, insects, etc., gains access to the system through superficial abrasions, wounds, and the pulmonary tract, and that a relatively small number of organisms may cause the disease.

Influence of Nephrectomy upon Absorption.—S. J. Meltzer and W. Salant have observed that in the many nephrectomies which they have performed on rabbits and guinea-pigs that œdema never followed this operation. Other experimenters have not recorded an increase in transudation after the removal of the kidneys. They, therefore, subjected the question as to the behavior of absorption after nephrectomy to an experimental test. The experiments were made on rabbits by introducing salt solutions through a fine opening into the peritoneal cavity and removing it very carefully again after varying intervals. There was a normal control rabbit for each nephrectomized animal. Lumbar nephrectomy was practised and care taken not to injure the peritoneum. The results were surprising. The absorption in the nephrectomized rabbits was distinctly better than in the normal. Then another factor was considered: the increased osmotic pressure of the blood after nephrectomy. As the urine has usually a higher osmotic pressure than the blood, it seems quite obvious that after nephrectomy the osmotic pressure of the blood ought to be increased. If this be correct, then a solution of 0.8 per cent. sodium chloride, which is about isotonic with the blood of normal rabbits, is probably hypotonic with the blood of the nephrectomized ones; hence the better absorption in the latter animals. Several other series of experiments were followed out with stronger solutions of sodium chloride. The absorption of a solution of 1.2 per cent. was in nephrectomized animals at least twenty-four times as good as that which took place in normal ones. Only in the series with 2-per-cent. solutions was there one case among the nephrectomized animals in which more was recovered than was introduced. These experiments clearly show that after nephrectomy absorption is considerably improved. The first effect, then, of complete anuria is not an increase of the normal transudation, but an increase of the power of absorption of the blood.

Philadelphia Medical Journal, January 24, 1903.

Spontaneous Rupture of the Heart, with a Report of Seven Cases.—Arthur S. Hamilton states that spontaneous rupture rarely, if ever, occurs in a healthy human heart. There are both predisposing and exciting causes, the former being a pathological condition of the heart, and the latter some mental or physical strain. The principal predisposing cause is some pathological condition of the coronary arteries, resulting in various changes in the heart muscle. Fatty degeneration is particularly common. Many writers believe that some acute, exciting cause can generally be demonstrated. It occurs usually in individuals past sixty. It may be either partial or complete. The most common seat of rupture is in the wall of the left ventricle, on the anterior surface, a little above the apex and a little to the left of the septum. Death from this cause usually occurs suddenly and unexpectedly, and often without diagnostic signs. Even in the most favorable cases of total rupture, accurate diagnosis is difficult. In every case the prognosis is highly unfavorable. Healing probably never occurs, and death is but a question of time. Treatment is of no avail, except to alleviate the pain, and possibly to prolong life for a short time. The patient should be made to rest completely with an ice-bag over the heart. Morphine should be given freely for the pain. Stimulants may be advisable in some cases, but any increased intracardiac pressure is apt to cause fresh hemorrhage. Digitalis might be beneficial by slowing the heart.

Atmospheric Pressure and Epidemic Influenza in Philadelphia.—Howard S. Anders presents several tables in his study of this subject. In the first table twelve non-epidemic years are represented, followed by twelve epidemic years. He states that comparative inspection and analysis of these two groups of figures fail to justify any generalization. A study of the mean maximums and minimums for the same groups of months and years shows uniformly lower maximums and higher minimums of recorded monthly means, for the epidemic, as compared with the non-epidemic group of years. Nevertheless, an abnormal increase in the barometric pressure (highest maximums) occurs decidedly at the times of greatest influential morbidity. In the same manner, it can be seen that the monthly means of the greatest ranges of barometric record (between highest and lowest points) show nothing characteristic. But, in the Weather Bureau records, the greater monthly absolute range was a marked feature of severe influenzal periods as compared with mild or sporadic years, the difference amounting to as much as four inches higher for the epidemic months. The table of average greatest twelve-hour changes corroborates the suggestion that any relation between meteorological conditions and the prevalence of influenza that may exist

will probably be found in the sudden, frequent, rapid, and extreme variations and alterations of the phenomena occurring on certain days, just before or simultaneous with the influenzal outbursts, and not in data of the means of large groups of monthly and annual recordings. The author concludes: "As in the case of the investigation of sunshine percentage, the behavior of atmospheric pressure in relation to epidemic influenza is characteristic in the marked lack of equability; in the absolute daily (sometimes almost hourly) extremes, and not in the monthly or yearly averages or means."

The Lancet, January 17, 1903.

The Restoration of the Inferior Turbinate Body by Paraffin Injections in the Treatment of Atrophic Rhinitis.—R. Lake details his experience with this method. It is based on the conception that the absorption of the turbinate is not due entirely to the atrophic rhinitis *per se*, but that crust formation and shrinkage are largely instrumental in such absorption. Hence, if we can restore the turbinates to their former shape and reduce the nasal passages to their normal width, this artificial construction will render the removal of discharge by irrigation easier, and enable the air current to exercise its physiological office on the nasal mucosa, for Lake believes that the friction caused by the passage of air through the nose is most beneficial in maintaining the parts in their normal condition. The paraffin is injected in the usual way and under the usual precautions. The results have been gratifying, the patients expressing themselves as feeling much relieved by the increase in the size of the turbinates.

Some Observations on Cyanosis.—The paper of C. A. Gibson has a twofold object. First to show what relationship exists between the conditions of the blood in the different divisions of the circulatory apparatus, and, in the second place, to indicate the results which have been obtained by the use of oxygen in cases of cyanosis. Two clinical histories are given in full, from which it is deduced that in cyanosis there is a general increase throughout the whole circulation in the amount of hæmoglobin and in the number of erythrocytes, while the state of matters as regards the leucocytes is less constant. Cyanosis is produced by the obstruction to the circulation and venous stasis. Under these changed conditions there is an altered function of the red cells. In venous stasis the corpuscles are insufficiently oxygenated, they cannot perform such an active part as oxygen carriers, and they cannot yield so much oxygen to the tissues. It must further be remembered that in cyanosis there is less metabolism in the tissues and therefore less waste produced. In a word, the functions of the corpuscles being lessened, the tear and wear which they undergo is reduced, and the duration of their individual existence increased. The number of the corpuscles must in this way be proportionately augmented, and this must lead to the numerical increase, as well as to the high percentage of hæmoglobin, until a balance is struck between the production and the destruction of the blood-corpuscles. Observation of cases of cyanosis as actually occurring seem to show that the use of oxygen is barren of results, for it is generally understood that the atmosphere ordinarily contains more oxygen than can be absorbed under any circumstances.

British Medical Journal, January 10, 1903.

Excision of the Tonsils During an Attack of Acute Tonsillitis.—Robert Bleasdale gives his recent experience with cases of this nature. He has had excellent results from removing the tonsils during an attack of tonsillitis, and is confident that the attack was cut short several days by this treatment, and the throat was in much better condition afterward than it would have been if the tonsils had remained. He now paints on the throat a 2-per-cent. solution of b. eucaine as the anæsthetic.

Acute Dilatation of the Stomach Without Apparent Cause.—David A. Belilios discusses the case of a healthy infant of nine months brought up entirely on the breast It was found dead one morning, two hours after it had been nursed and put to bed. Nobody had been in the room. There was an entire absence of symptoms of any kind. Autopsy revealed a distended stomach. There was no stricture of the pylorus or adhesions. The duodenum was not dilated. There were no signs of inflammation of the gastric mucous membrane, and there was in the organ only a small quantity of clotted milk.

Three Cases of Acute Intussusception in the Same Family.—Robert G. Riddell describes these cases which occurred in a family of four children, one ending fatally, and two being relieved by operation. In each case there was a history of digestive troubles, probably due to careless feeding, and in two increased by dentition. It could not be determined at operation if there was any congenital condition common to all three, though this might be expected. It has been suggested that an abnormally movable cæcum predisposes to ileocæcal invagination, while a cæcum firmly fastened down may give rise to the ileocolic variety. It can also be conceived that when one part of the bowel is abnormally fixed, and an adjacent movable segment is thrown into violent peristalsis, an intussusception may be produced. But whatever the cause, it must be considered something more than a mere coincidence that this somewhat rare affection occurred in three children out of four in the same family.

Four Cases of Duodenal Ulcer Perforating Acutely.—D'Arcy Power draws the following lessons from these cases which he reports: (1) Duodenal ulcers occur more often in men than in women. (2) The extravasated fluid trickles into the iliac fossæ and causes a local peritonitis, which may be mistaken for an acute appendicitis. (3) The transparent or bile-stained succus entericus found in the peritoneal cavity is diagnostic of a perforated duodenal ulcer. It is quite different from the gastric contents escaping at a perforated ulcer of the stomach. (4) The prognosis of a duodenal ulcer is worse than that of a perforated gastric ulcer on account of the greater difficulty in closing it satisfactorily. (5) The prognosis should not be too sanguine until after the lapse of the eighth day, and it is always bad, however well the patient may appear, if the pulse-rate continues rapid. The pulse is a much better guide than the temperature. (6) Free drainage is imperative, both iliac fossæ, the recto-vesical pouch, and the space below the liver more particularly need tubes. It is better that the patient should recover with a scarred belly than that he should die with an abdomen full of pus. (7) The feeding of the patient is a matter of great importance. Small quantities of food should be given frequently, and if the patient feels sick the amount must be reduced at once. It is better to give nutrient enemata for some days after the operation than to administer food by the mouth.

British Medical Journal, January 17, 1903.

Removal of an Ovarian Fibroma from a Patient Aged Seventy-three Years.—Frederick J. McCann reports this case, which is of interest not merely because of the age of the patient, but because the history shows that a solid ovarian tumor may exist and increase in size after the climacteric, and yet be simple in character. It is probable that the new growth did not appear until after the cessation of menstruation. The first time the patient noticed that anything was wrong was in alighting from an omnibus one day when she felt a sensation as if something had "given way" in her abdomen. After this she felt a hard substance in the lower abdomen, and a sensation of weight in that region. The growth, which increased in size, soon interfered with the functions of bowels and bladder. Life became such a burden that the patient was anxious to undergo anything in preference to the suffering she was then enduring. At operation the tumor was found wedged into the pelvis. It was attached by a long, slender pedicle. The ovary on the left side was atrophied. There was no ascites. The pedicle was ligatured, and the tumor which grew from the right ovary was removed. The pelvic cavity was flushed with hot salt solution and the parietal wound closed. The patient made a good recovery.

A Clinical Lecture on Two Cases of Chorea Gravidarum.—D. Berry Hart describes these cases. The first patient was eighteen years of age and two months pregnant. She had had one child, which lived a month. The attack originated from a fright which she had from seeing a mouse run out of a closet by which she was standing. The father had been a heavy drinker, and the mother seems at one time to have had epileptic fits. She had never had chorea in her childhood. After she was brought to the hospital, she was never at rest while awake. She was mentally acute. Apart from her nervous disturbance, her systems were healthy. The ordinary remedies brought little or no relief. The patient developed delusions, and became so noisy that abortion was decided upon. Great care must be taken in this matter. Antiseptic precautions must be most carefully observed. Tupelo tents were inserted into the cervix, removed in twenty-four hours, and the dilatations completed with vulcanite dilators. The fingers of the right hand were passed into the vagina, the middle one being passed into the uterine cavity. The uterus was cleared out bimanually, washed out, and, together with the vagina, plugged with one long strip of iodoform gauze which had been kept in biniodide of mercury solution (1:3,000). There was no special hemorrhage. The next day the tampon was removed, and the uterus washed out. The result of the abortion was very marked. The chorea gradually passed off, and she finally made a perfect recovery. The second case was not so serious, and was treated by large doses of antipyrin. She was given sodium bromide and antipyrin, 15 gr. of each, four times a day. The beneficial effect was soon manifest, and she left the hospital quite well.

Deutsche medicinische Wochenschrift, December 25, 1902.

Influence of Temperature and Season upon the Occurrence of Primary Glaucoma.—Kurt Steindorff studies this question upon 102 cases. Of these, the smallest number occurred during the months of June, July, and August, and the largest number during January, February, May, and December. The explanation of the more frequent occurrence of primary glaucoma in the cold weather is not entirely clear. The intraocular pressure is dependent to a certain degree upon the general blood pressure, and it is well-known that the latter is higher during cold weather than warm. Also the pressure of the external air is, as a rule, higher in winter than in summer. The frequent so-called "colds" and catarrhal conditions which are prevalent in winter also exercise, in all probabilty, a certain influence. The practical importance of this subject consists in the endeavors which should be made to protect those predisposed to glaucoma during the winter season by sending them to warmer climates, similarly as is advocated in rheumatism and various other diseases.

Tremor and Urine Intoxication.—Alfred Hock reports a case which shows how partial retention of urine may give rise to severe nervous and general phenomena. The patient was an elderly man and sought medical advice on account of a severe generalized muscular tremor, marked digestive disturbances, and increasing prostration. All of these symptoms had been present for some time and had resisted treatment which had been employed. Hock at first diagnosed the case as one of tremor senilis, but upon subsequent examination the prostate was found to be enlarged and a considerable amount of residual urine present in the bladder. The only urinary symptom present was increased frequency of urination. From this time on the bladder was emptied at frequent intervals by catheterization. This resulted in a marked improvement in all the symptoms and a complete disappearance of the tremor. About five months thereafter the patient died from marked pulmonary lesions, the character of which is not stated. Shortly before death the tremor returned. The reappearance, however, is to be ascribed to deficient renal excretion occasioned by cardiac weakness. It seems certain that the original tremor was due to intoxication caused by the retained urine.

A New Bacillus of Syphilis.—Max Joseph and Piorkowski adds seventeen cases to the twenty-two which were reported by them in the *Berliner klinische Wochenschrift* of March 5, 1902. In all of these thirty-nine cases of active secondary syphilis a hitherto undiscribed bacillus was isolated from the spermatic fluid. The only way in which such solution was successful was by cultivating this fluid upon sterile placenta at the incubator temperature for two or three days. In the secondary generation the bacilli could be grown upon the ordinary artificial culture media. Upon such, however, they soon showed degenerative appearances and, unless retransplanted upon human media, soon died. With Loeffler's methylene blue they stain almost identical to the diphtheria bacillus; in size, however, they correspond to the bacillus subtilis. They stain positive with Gram. They are not pathogenic for the ordinary laboratory research animals. They are non-motile, coagulate milk, produce an abundant sediment in bouillon and grow in a white, shining layer upon potato. They produce neither gas nor indol, and spore formation has not been observed. They do not fluidify gelatin. These bacilli have never been cultivated from the spermatic fluid of normal men or of those suffering from tertiary syphilis. Fifteen of the former endeavors have been made and eleven of the latter. On the other hand, this bacillus has been frequently isolated from the mucous patches and enlarged inguinal glands of secondary syphilis. The effect of the administration of mercury upon the presence of the bacillus in the spermatic fluid is varied. In some cases under such treatment it soon disappears, while in others it remains for a long time. The authors think that the facts already produced warrant the assumption that this bacillus is the causative agent in the production of syphilis; they are, however, continuing their observations and adding more cases in order to make their contentions absolute.

Deutsche medicinische Wochenschrift, January 1, 1903.

Are Streptococci Present in the Mouths of Breast-fed Infants?—Julius Herzberg says that they are very frequently, if not constantly, so present. Ten infants were examined, of which eight were dispensary and two private. In all streptococci were isolated. The length of the chains varied. Many streptococci which were short-chained in the first generation, became long-chained in the second. It is hence evident that streptococci cannot be properly subdivided into short and long-chained species, as has been done by Lingelsheim, since these forms are undoubtedly transferable. In one-half of the cases cover-glass preparations made directly from the throat or tonsils did not show streptococci, although cultures made at the same time regularly showed their presence. Mice and guinea-pigs (number not stated) were in oculated intraperitoneally with pure bouillon cultures of the streptococci. Four of the mice thus inoculated died.

Cardiac Hypertrophy in Nephritis.—H. Senator gives his views concerning the origin of cardiac hypertrophy in nephritis, and in such the excessive hypertrophy of the left over the right ventricle. In chronic parenchymatous or subacute nephritis, on account of lessened functional renal activity, the blood becomes surcharged with deleterious nitrogen extractives. The walls of the vessels are injured thereby and undergo various degenerations. As the result of this the vessel walls transmit fluids more readily than normal, and dropsies appear in various locations. The various degenerations mentioned also result in a contraction of the vessels. This contraction, together with the pressure of the dropsical fluid markedly increases the work of the heart, and especially that of the left ventricle, for it is known that the changes mentioned occur last of all in the lung, so that the right ventricle is not called upon for extra work until long after the left ventricle has been obliged to perform the same. In this manner the cardiac hypertrophy and the excessive hypertrophy of the left ventricle is to be explained. In acute nephritis the amount of nitrogen extractives retained in the blood exceeds that present in the chronic form. In the former, however, the renal activity is, as a rule, soon restored and a normal condition reëstablished in the blood vessels before permanent damage has been done to the heart. In those cases of acute nephritis which pass into the subacute or chronic form, the same vascular and cardiac changes take place as above described. In chronic interstitial nephritis the causes of the cardiac hypertrophy are the same as in the chronic parenchymatous form. In the former, however, the hypertrophy appears much later than in the latter, because the renal activity is much more slowly damaged and consequently the amount of nitrogen extractives retained in the blood is much less.

Berliner klinische Wochenschrift, December 29, 1902.

Alopecia Areata.—E. Richter reports a case which substantiates the view that alopecia areata may be caused by an injury of division of the second cervical nerve. The patient was a female, fifty-two years of age. The previous history was good. The patient received a fall which resulted in a fracture of the second cervical vertebra. As sequels there developed a persistent neuralgia, and one and a half years later the development of two characteristic lesions of alopecia areata. In spite of all treatment the latter remained permanent. By careful exclusion no other cause could be discovered for the alopecia than the fracture of the vertebra above mentioned.

Surgery in Warm Countries.—Hans Ziemann reports a remarkable cæsarean section which was performed in Western Africa by a midwife. No anæsthetic was used, and the asepsis must have been very crude. The abdominal incision was made transversely. Both child and mother were saved. The uterus was not sutured. The abdominal wall was closed with catgut. Very little fever developed after the operation. Small doses of quinine readily controlled what little elevation of temperature there was. The patient was a white woman, but had been in Africa for some years. The author has often observed with what apparent impunity the residents of Africa withstand major surgical operations, but is not able to offer any explanation therefor.

Münchener medicinische Wochenschrift, Jan. 6, 1903.

Tuberculosis of the Optic Nerve.—V. Michel describes the pathological lesions. Tuberculosis of the optic nerve is chiefly met with in childhood. It may affect any portion of the nerve from the chiasma to the retinal ramifications. Blindness may or may not be present, according to the location of the lesions and the portion of the nerve involved. The retinal picture often shows miliary tubercles. When these are not present this picture corresponds to that of neuritis, atrophy of the papilla, or choked disc. The prognosis is, of course, fatal.

Primary Actinomycosis of the Tarsal Bones.—O. Bollinger reports a rare case. The patient was sixty-four years of age and had suffered for many years from periodical attacks of inflammation, swelling, and soreness in the left tarsal bones. These attacks had gradually increased in intensity and duration, so that at the time of his coming under observation walking was impossible. A diagnosis of purulent osteitis and necrosis of the tarsal bones was made and was thought to be tuberculous in nature. The foot was amputated. Upon examination no tubercle bacilli were found, but actinomycetes were isolated in pure culture. Recovery followed, no other pathological lesions developing in any region of the body. The date of infection was

supposed to date back many years to the time at which an injury to the foot was received while the patient was making a long march as a member of the army.

French and Italian Journals.

The Weight of Lecithin in Milk.—Bordas and Rackowski have been investigating the effect of various methods of heating milk, on the amount of lecithin contained in it. They have determined this question, which is one of great importance in the feeding of children. When milk is heated in a vessel that is placed directly over the fire, the lecithin contained is diminished one-third, while milk heated in a double boiler has its lecithin decreased only one-sixth. The natural teaching of these observations is that it is always important to heat, in a double boiler, milk intended for a child's feeding.—*La Presse Médicale.* January 7, 1903.

Treatment of Neuralgias by the Injection of Sterilized Air.—Marie and Crouzon are using a very simple apparatus for the injection of sterilized air. The results of this treatment are remarkable. In one case of sciatica, which had proved very rebellious to treatment, an injection of sterilized air at three or four of the painful points caused the disappearance of all the pain. In a case of herpes with intense neuralgia the cure took place after one injection—the same result took place in a tabetic, who had long suffered from persistent pain. In all of these cases the cure was final. The quantity of air injected varies from ¼ to ½ a liter. The mode of action is not known. Perhaps the air which is injected into the cellular tissue acts by spreading out the nerve filaments and causing an elongation of the nerve ramifications.—*La Tribune Médicale*, December 17, 1902.

A Case of Pseudarthrosis Treated by Freshening and Suture of the Fragments.—Bérard reports the case of an alcoholic patient, thirty years old, who, after having a fall, lay for seven hours before help arrived. The femur had been broken at its middle part, and the upper part had pierced the tissues. Approximate reduction was performed a plaster bandage fitted, and continuous traction applied. Suppuration followed for four months, but there was no consolidation. Ten months after the accident the leg was atrophied and the joints eroded. Radiography disclosed the presence of necrosed splinters between the fragments. Continuous extension reduced the shortening from 10 to 7 cm. Intervention was necessary, and the splinters were removed. Reduction was accomplished by the resection of 1 cm. of each fragment with a V-shaped notch in the lower fragment, which received the point of the upper fragment. The fragments were sutured and a splint applied. After three months there was perfect consolidation, with a shortening of 5 cm. —*Lyon Médical*, December 7, 1902.

Calcium as a Hæmostatic.—P. Regoli has found by his researches that the salts of calcium accelerate the coagulation of the blood only when it is deficient in calcium, for the addition of calcium to normal blood not only does not hasten coagulation, but interferes with the process, whereas it causes or increases coagulation, if the blood has previously been deprived of its calcium. From this fact we see that the question as to the usefulness of calcium as a hæmostatic is much more complex than appears at first, depending as it does upon peculiar clinical conditions. Moreover, we have to take into consideration the absorptive powers of the various preparations of calcium, and the method chosen for their introduction. The general physiological properties must also be borne in mind, especially when the endovenous method of administration is chosen. It will be seen that there are decided limitations to the use of calcium as a hæmostatic.—*Rivista Critica di Clinica Medica*, December 20, 1902.

The Separation of the Urine of the Two Kidneys.—Georges Luys gives some very interesting observations which he has made while using the little instrument which he calls his separator. It consists, essentially, of two hollow sounds, with orifices on their internal surfaces. These sounds are connected by a third part, and they are all provided with a rubber covering. It is of the greatest use in surgical cases to show which is the diseased kidney, and especially to show the functional condition of the kidney, which is supposed to be healthy. In medical cases it will show to what extent each organ is diseased. In every case in which the clinical signs and the results of the separation disagreed, surgical intervention showed that the separation had furnished perfectly correct data. One case noted is of considerable interest in this regard. All of the clinical signs tended to show that the right kidney was tuberculous, and indicated that that organ ought to be removed; on the contrary, the separator showed the right kidney to be the healthy one. Nephrectomy of the left kidney proved it to be completely atrophied and having no functional value.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, December 11, 1902.

Botryomycosis.—Savariaud and Deguy give this name to a parasitic affection. In man it is attended by pediculated tumors of the skin, which are filled with mulberry-form masses. Cultures of this give a micrococcus, which, up to this time, has been considered specific, the micrococcus botryogenes. Until recently the affection has been studied exclusively by veterinarians. In 1897 it was suspected to be present in a man. Sometimes the affection appears spontaneously, but more often the small tumor arises at the site of a septic inoculation, from a prick, for example. The course is rapid, generally a few months. As to treatment, ablation, pure and simple, is the only method. The tumors develop generally on the fingers. Bacteriological examination shows that they contain sometimes one kind of coccus only, botryococcus, or staphylococcus, while at other times the micrococcus is associated with different bacteria.—*Revue Française de Médecine et de Chirurgie*, January 5, 1903.

A Case of Cancer Originating from a Cicatrix.—Vittorio Martinelli reports the case of a man who, twenty years previously, had been seriously wounded in the leg by revolving machinery; the wound had healed very slowly and a large cicatrix remained. A few months before being seen by the author a heavy beam fell upon the leg, producing an extensive wound at the site of the cicatrix, with copious hemorrhage, which kept up for several days. As the wound did not heal, the physicians in charge of the case cauterized it with the actual cautery, and as the wound still continued to spread, they repeated the cauterization three times. The author was then called in consultation, and found a lesion which could not be considered as a simple ulceration, but from its rapid propagation, the frequent hemorrhages, the presence of epithelial masses, the appearance of nodules on the surrounding skin, and the swelling of the inguinal glands was diagnosed as a malignant neoplasm. The general condition was one of cachexia. The leg was amputated at the knee, and twenty months later the patient was in excellent condition. By examination with the microscope the growth was found to be an epithelioma.—*Giornale della Associazione Napoletana di Medici e Naturalisti*, September-October, 1902.

The Remote Sequelæ of Cerebrospinal Meningitis.—Widal and Lemierre discuss this question. Cases of this affection have been reported in which recovery was complete; while in others have been noted certain nervous troubles (deafness, muscular atrophy, incomplete paralysis) persisting some time after the cure of the acute meningitis. They report the case of a man, recovered now four years from an attack of suppurative cerebrospinal meningitis, which was diagnosed at the time by lumbar puncture. Since his recovery, the pursuance of his work has been laborious, and he hesitates in walking. At various times he has had sudden attacks of lumbar pain, as well as pain in his legs, for the relief of which he has been to the hospital several times. When he came under the care of Widal and Lemierre, he was suffering from intense lumbar pains and from a sciatica of the left leg, with Lasègue's sign and the classical painful points. Lumbar puncture revealed a slight but distinct lymphocytosis, which showed that there was a persistent meningeal irritation. It is interesting to connect this lymphocytosis with the nervous troubles which have recurred almost periodically for four years—that is, since the cure of the acute cerebrospinal meningitis.—*Le Bulletin Médical*, January 3, 1903.

Tuberculous Peritonitis.—Veit concludes that tuberculous peritonitis is always secondary. Two forms can be distinguished—the ascitic and the adhesive. The affection of the genital organs may be primary, and it may consist of tuberculosis of the peritoneal covering of the genital organs only. Peritonitis with extensive nodules, that can not be attributed to ovarian tumors or to carcinoma, ought, as a rule, to be regarded as tuberculous. Tuberculous peritonitis may be cured spontaneously, but this is rather rare. Tuberculous peritonitis is cured by laparotomy, although some unsuccessful cases have been noted, generally on account of the advanced tuberculous affection of other organs. There is not a unanimity of opinions in the explanation of these recoveries. The influence of normal serum, or antitoxic, is a very probable explanation. In recent cases there should be operation if the peritonitis causes pain; and a repetition of the operation may become necessary if the first one has been very early. Chronic cases ought to be under observation from the first; if spontaneous recovery is delayed, intervention is necessary. Operation consists in simple laparotomy in the linea alba, in the complete evacuation of the liquid and in the suture of the operative wound. Radical abdominal operation ought to be done only when at the same time there is found genital tuberculosis completely isolated.—*Gazette de Gynécologie*, January 1, 1903.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-seventh Annual Meeting, Held in Albany, January 27, 28 and 29, 1903.

HENRY R. HOPKINS, M.D., OF BUFFALO, PRESIDENT.

FIRST DAY—TUESDAY, JANUARY 27.

THE sessions were held in the Council Chamber of the City Hall, Albany. The meeting was called to order by the President, Dr. Henry R. Hopkins of Buffalo, and the session was opened with prayer by the Rev. Father Oliver.

President's Inaugural Address.—Dr. HENRY R. HOPKINS delivered this address. He said that in the charter granted the society in 1806, and in all the earlier amendments of that charter, the composition of the society, as determined by the number of delegates that might be sent by county and other societies, was cautiously, jealously, and wisely guarded. It was his profound conviction that to this wise provision of the fathers this society owed its century of existence, and its well-established reputation for conservatism.

Renouncement of the Code of Ethics.—One of the most important and wisest steps taken by this society had been the renouncement of the Code of Ethics, a document of much value, dignity, and importance, but one containing certain faults, bad philosophy, and vicious tendencies. This action of the society was a virtual acknowledgment of an error in judgment on the part of the society, and a distinct proclamation that hereafter the members would be careful that they were governed by the laws of this State. This had led to an important law whereby the society was given the authority to regulate and control its own membership, and as a result, it had been enabled to increase more than fivefold its number of delegates. The crowning enactment in its favor was that giving the society authority to examine those applying for a license to practise medicine in this State.

Organization of Nurses.—Mention was made of the fact that a bill was to be introduced into the Legislature asking that trained nurses be licensed by the State in accordance with rules prescribed by the Board of Regents. The speaker was of the opinion that this movement was wise, timely, and in good hands, and deserved the hearty support of this society. He advised that the matter be referred to the Committee on Legislation, with instructions to support the measure in the Legislature in every way possible.

Hospital for Consumptives.—After long and discouraging delay, definite progress was now being made in the establishment of a State sanatorium for incipient cases of consumption. A building to give accommodation to 100 patients was now under contract.

A New Degree Suggested.—It was suggested that, in imitation of the custom prevailing in Great Britain, the degree of D.P.H.—"Doctor of Public Health"—be granted to those who had properly qualified themselves by the study of hygiene and sanitary science.

Unity of the Profession.—The speaker said that for many years the society had earnestly and consistently worked to secure the union of the three "systems" of medical societies in this State. A final campaign in this cause had been inaugurated by his predecessor in the chair, by the appointment of a committee of conference. As an incident of this campaign to restore legal medical unity this society had been without representation in the American Medical Association for many years. Because of the encouragement received by the reorganization on a broad platform of the American Medical Association, it seemed desirable that the society should make an overture in the direction of the resumption of diplomatic relations with the national body. The untimely death of Dr. A. M. Phelps had created a vacancy on the committee of conference, which had been filled by the appointment of Dr. Frank Van Fleet of New York. The unseemly and undignified divisions of the medical profession of this State were not a credit to the profession. He thought it would be well if this whole matter could be adjusted before this society should complete its present century. It was still more important that this settlement should be made with due regard to the rights of the minority, but this society could never agree to the sacrifice of those principles which had been maintained so long, and which had been the means of placing this State society prominently before the country and the world, with regard to the requirements for the right to practise medicine in this State.

Report of Committee on Hygiene.—Dr. JOHN L. HEFFRAN of Syracuse presented the report. It stated that tuberculosis continued to be the most prevalent of the preventable communicable diseases. From the fact that in recent years there had been a reduction in the death rate from tuberculosis in Great Britain of 45 per cent., and in New York City of 40 per cent., it was evident that this disease must be looked upon as very easy of control. This was still further emphasized by the report of Dr. Bowditch to the effect that, at the sanatarium at Rutland, 79 per cent. of the cases received in the first stage of pulmonary tuberculosis were arrested. The committee urged the society to exert itself to preserve all the good points of the present tenement-house law, and recommended the registration, by physicians, in proper offices, of every case of pulmonary tuberculosis, and the disinfection of premises after deaths from tuberculosis, by the health authorities. It was also recommended that receiving hospitals for tuberculosis be erected by each community, and be independent of the county poor-house. The Committee on Legislation was asked to secure the passage of a law which would allow of the appointment as health officers of only those showing special fitness for such duties.

The Tenement-house Law.—On motion of Dr. GEORGE B. FOWLER of New York the following resolution was adopted:

Whereas, Strenuous efforts are being made to induce the Legislature to utterly undo the great advances made in recent years in tenement-house reform and sanitation, and to prevent the permanent carrying into effect of the great improvements in the construction and management of tenement-houses in New York and Buffalo, which has been made possible by the recent Tenement-House Law; and

Whereas, Pulmonary tuberculosis is practically epidemic in the City of New York, there being eight thousand deaths and twenty thousand cases annually; and

Whereas, The lack of light and air in the rooms of the great masses of the people is one of the most potent causes in increasing the prevalence of this and other communicable diseases and constitute serious menaces to health and morality,

Be it Resolved, That the Medical Society of the State of New York deplores any weakening of the present Tenement-House Laws, and urgently requests the Legislature to permit no changes to be made that will in any way decrease the amount of light and air available for the people living in such houses, or in any way take a backward step in regard to their sanitary conditions.

Report of the State Board of Medical Examiners.—Dr. WILLIAM WARREN POTTER of Buffalo presented an abstract of this report: "The total number of candidates since the establishment of this board eleven years ago was 7,034, of which number 5,528, or 78.5 per cent., were successful, and 1,506, or 21.4 per cent., unsuccessful. The total number for the last academic year was 928, of which 685 applied for license, and 558 were successful. Of the number appearing before this board, 17.8 per cent. were rejected; of those appearing before the Homœopathic Board, 13.2 per cent. were rejected, while 50 per cent. were rejected by the Eclectic Board. The yearly average number of candidates appearing before these respective

boards was 586, 46, and 16. The board expressed itself as in favor of some action by which old practitioners from other States could be more leniently dealt with in regard to examination in the primary branches. The board recommended that the degree of "D. P. H."—Doctor of Public Health—be conferred.

Report of Committee on Unification of the Profession.—Dr. Henry L. Elsner of Syracuse presented this report. After reviewing the preliminaries and reading in full the correspondence, the report went on to say that the committee of the State Society was from the first impressed with the fact that the committee from the State Association was sincere and earnest in its effort to secure unity of the medical profession of this State. The latter committee held that the reorganized society must of necessity apply to the Legislature for a new charter, and accordingly the committee of the State Society obtained a legal opinion from Mr. Charles Andrews. This was to the effect that the State Society had power to change its by-laws by vote of the Society and without application to the Legislature. The Society could amend its constitution and by-laws without further legislation, and could incorporate into its membership all members of county societies; hence, the New York State Medical Association, if it so determined, might abandon its present organization, and its members might become members of the Medical Society of the State of New York by a change made by the latter society in its by-laws regarding the conditions of membership. It was thought to be important that this union should be effected without abandonment of the charter of the Medical Society of the State of New York, which had existed for nearly one hundred years. It was also held that the abandonment of the present charter of the Medical Society of the State of New York would end its existence. Continuing the report, the speaker referred to the revision of the by-laws of the American Medical Association, and said that, at the adjourned meeting held in Chicago, shortly after the Saratoga meeting, Chapter XV. no longer appeared in the revised by-laws, yet he had been assured by the present president of the American Medical Association that the Code of Ethics was still in existence and unchanged. Dr. Billings had also assured the committee of the State Society that the Code of Ethics of the American Medical Association would not be considered binding upon the State Association, but the committee did not feel that it could yet withdraw its former objections to union. It was true that in the unification of two powerful State bodies, such as the State Association and the State Society, many complex problems arose. The will of the individual members of the profession must be learned. Among the plans for reorganization thus far suggested might be mentioned a scheme by which all members of county societies become members of the State body, thus abolishing entirely the delegate system. Another scheme was to reorganize the State Society so as to extend it to the members of the New York State Medical Association, with a continuance of the county societies and the delegate system. Another plan, and one which would probably be presented to the American Medical Association at its coming meeting, was that by which all members of county societies, by the payment of a single fee to the State treasurer, become members of both the State and National bodies. This was the plan to which the American Medical Association had recently been lending its influence, and it contained the elements which tended to secure unity of the profession throughout the county. The committee entered an emphatic protest against the resolution introduced by Dr. E. D. Ferguson of Troy at the October meeting of the New York State Medical Association, and adopted by that association. The part especially objected to was the resolution that "if the Medical Society of the State of New York shall fail to approve such plan of union by a charter to be secured at the approaching session of the Legislature in 1903, then this committee shall be considered as discharged, and the proposition of the association withdrawn." The committee of the State Society felt that it could not consent to the time limit thus insisted upon, believing that the spirit was not in keeping with the earnest desire for unity and harmony so often expressed at the previous conferences. Quoting from the report of the treasurer of the State Association, it was shown that the publication of the *New York State Journal of Medicine* and of the "Medical Directory," which latter was characterized as a useful and worthy publication, had been carried on at a great financial loss to the State Association, and it was argued that the reorganized State bodies could not maintain this costly work, for, it should be remembered, the income of the united State bodies would not equal the combined incomes of the present association and society, because of the surprisingly large proportion of members who were affiliated with and paid dues to both bodies. The committee declared that it could not consent to any arrangement which would in any way interfere with the life of the Medical Society of the State of New York. The Code of Ethics being still in existence, the Committee did not feel that it was in its power to recommend that action be taken by the Medical Society of the State of New York until the American Medical Association should make it possible for that society to subscribe to its constitution and by-laws and written rules of order, and could do this consistently and without sacrifice of principle. In conclusion, the committee reported progress and asked that its report be received and that further time be given to the committee to prosecute its work."

The report of the committee was received amid great applause. On motion of Dr. F. R. Sturgis the committee was continued, with instructions to ascertain what further action could be taken in the matter and to report at the next meeting of the State Society. It was also voted that this report be printed immediately and a copy sent to every member of every county society in the State

Arguments for the Existence of a Separate Cortical Center for Writing.—Dr. Herman C. Gordinier of Troy presented this paper. He said that there were two principal views on this subject. The older one was that the focal corticle center for writing did not exist. The other view maintained that the act of writing was independent of the faculty of expression by articulate speech, and that when it was in abeyance it was because of the destruction of a cortical center probably situated at the base of the second left convolution. In support of this view the speaker said that sufficient pathological and clinical data existed to show that destruction of Broca's center did not necessarily cause agraphia. Trousseau had stated that the inability to write was in proportion to the inability to speak. To show the fallacy of Trousseau's reasoning, the author introduced citations from various clinical reports, including one made by Trousseau himself. Four cases were reported, the only ones known by him to exist in literature, in which there was motor agraphia and motor aphasia with a pathological lesion at the base of the second and third left frontal convolutions. Isolated motor agraphia, though very rare, certainly did occur. The author reported a case of his own, one of glioma at the base of the second left frontal convolution.

Medical School Inspection in the City of New York.—Dr. Henrietta P. Johnson of New York presented this paper. She said that the system of medical inspection of the schools of New York City had been organized by the Board of Health, the city being divided into thirty-five districts. One hundred and fifty men and women were selected as inspectors from the civil service list. In the first year of this work, 108,638 examinations were made, and the total number of exclusions for all diseases was 6,829. On the day the schools opened in the fall of 1900 there were presented 100 cases of catarrhal con-

junctivitis in one school. In September, 1902, a new method of school inspection was adopted. This required daily morning observations as before, and in addition a weekly examination of every child in every class. The examinations included inspection of the eyes, throats, and hands. From December, 1902, to January 11, 1903, a period of twenty-five days, there were 950 new cases of trachoma presented for treatment, and 127 operations were performed.

The Care of the Insane.—Dr. CHARLES G. WAGNER, of Binghamton read this paper. He compared the old régime with the modern one, and showed the beneficent results of the earnest and persistent preaching of the gospel of non-restraint. The hospital for the insane of to-day, instead of being like a prison, was more like a thriving town. The fundamental principle of the new treatment was the greatest personal liberty consistent with safety. Occupation was the keynote of the care and treatment after the acute stage had once passed, and by such means the germ of hope was implanted where before was nought but despair. The acute cases should be carefully examined, the causes of the mental disturbance ascertained and noted, and then rest and quiet enjoined together with the most nourishing diet. A skilful and tactful nurse could often persuade those patients to take the requisite amount of nourishment. It would often be found that ten or twelve eggs a day would prove a useful addition to the diet.

Differential Diagnosis of the Familial Forms of Spinal Disease.—Dr. FLOYD S. CREGO of Buffalo was the author of this paper. As a general rule, hemiplegias were the result of brain disease, although sometimes due to spinal disease. The commonest of all diagnostic errors was the confounding of functional and organic diseases of the cord. It should be borne in mind that the prominent symptom was the functional or hysterical lesion, but under this would be found the organic lesion. Thus, paraplegia, occurring in hysterical patients, was not necessarily functional, and might have an organic basis. The symptomatology of acute myelitis was varied. The more common form was complete transverse softening, involving the mid-dorsal region. There was complete anæsthesia below the front of the lesion, and the muscles gradually wasted. The reflexes were greatly exaggerated, and marked ankle clonus was present. As the disease increased, all four extremities became paralyzed. In lumbar myelitis there was loss of the reflexes, instead of an exaggeration. This disease was often mistaken for Lander's disease—an acute ascending paralysis. The cause of the latter was probably some toxic principle, having an affinity for the nervous system, as post-mortem examinations, in such cases, had uniformly yielded negative results. In this disease there was gradual loss of power; in myelitis there was a rapid loss of power and sensation. In hysteria one would find patches of anæsthesia, and with hysterical paralysis there was no analgesia, and no loss of the heat sense.

Erythrophlœum: A Clinical Study.—Dr. REYNOLD W. WILCOX presented this paper. He said that this drug acted very much like digitalis in many respects. It enormously increased the blood pressure, and slowed the heart; it increased the rapidity of respiration, while it obliterated the respiratory oscillations in blood-pressure. He had found that the drug was indicated in cases showing a rapid heart action, with low tension and venous congestion. Its use was contraindicated in extremely weak hearts. It was chiefly useful in rather stout persons, suffering from tachycardia, and in cases exhibiting a fair degree of compensation, and in which digitalis had failed. It possessed the advantage over digitalis of greater rapidity.

Observations on American Climates and Localities in the Treatment of Pulmonary Tuberculosis.—Dr. JAMES K. CROOK of New York read this paper. It was his opinion that the scourge of tuberculosis would eventually be mastered by the science of the human race, as the nature and causes of the disease were adequately understood and it was known to be preventable, and morbidity tables were already being influenced in some localities by sanitary measures recently put in operation. For a very considerable period to come, however, the present ratio, of one death from tuberculosis to seven from all causes, would probably not be materially altered. It would thus appear that, of the present population of the United States, something like 10,500,000 would succumb to phthisis. The reader of the paper thought that no other measure, or combination of measures, which might be called into operation would occupy so important a part in the war being waged against this disease as a proper appreciation and utilization of the value of climatic treatment. Instead of recommending a change of environment as a last resort, as was at present so often done, this step should be taken as soon as the presence of tuberculosis was recognized. If this were not done the chances that the disease would progress were about 99 in 100. The fact that the bacillus had been able to gain a foothold in the patient's system indicated a favorable relation between his environment and the bacillary growth, and, as a rule, but one outcome could be expected. Within the confines of the United States could be found typical examples of all the best forms of climate possessed by the old world. Some of these localities were within very easy reach of New York City. The trouble was the profession had been tied down to two or three climatic regions, which, though valuable enough in properly selected cases, had lost some of their reputation as a result of an indiscriminate influx of all kinds and conditions of tuberculous patients, many of whom would have been better off had they remained at home. The reader of the paper then briefly outlined some of the available climatic areas of the United States, many of which, though at present scarcely utilized at all for the purpose, would be found as efficacious in arresting the progress of tuberculosis as the best of the old-time resorts. The reader was not in favor of "throwing physic to the dogs" and blindly relying upon climate alone. The latter, he stated, could not be regarded as a specific for consumption, but only as one of our most highly-prized aids. While reposing much hope and confidence in the value of climatic change, he would at the same time not disregard the undoubted value of certain pharmaceutical preparations, of good food and of proper hygiene. If it were possible to place each patient without delay under an environment uniting good air, good food, good sanitation, and skilful medical supervision, a long step would be taken in the direction of overcoming the ravages of the disease. The patient would not only thus have the best opportunity for recovery, but would cease to be a menace to his associates and to the community at large. This, he said, could only be brought about by the establishment of properly equipped sanatoria in localities having the requisite climate, and this, he considered, to be a *sine qua non*. The most important condition of all, proper air, could not be brought into the city; and hence it became necessary to seek it in its habitat. Dr. Crook did not decry the many benefactions donated of recent years by our philanthropists to various purposes, but it was his firm conviction that the rich man who would establish and endow one sanatorium, where his suffering and dying fellow creatures might be won back to health and strength and usefulness, was worthy of greater love and honor from his countrymen, and would occupy a higher place in the Final Accounting than he who embellished a costly church, built a library, or founded a university.

Retinoscopy.—Dr. D. H. WIESNER of New York read this paper. He described the retinoscope as consisting of a plain mirror of glass, circular in shape, and about one and one-half inches in diameter, mounted on a handle and having a central aperture in the mirror. The source of illumination, preferably an Argand burner, should be to the right of the patient and at a distance of forty inches.

Using the retina as a point of illumination, the rotation of the mirror showed whether or not the refractive condition of the eye was normal. Both the horizontal and the vertical meridians should be studied. When the illumination moved *with* the rotation of the mirror in both meridians, it indicated that the eye was hyperopic. When the movement of the illumination was in a direction *opposite* to that of the mirror, the case was one of myopia. Simple hyperopic astigmatism, if not too high, could be recognized by the illumination assuming the form of a band of light instead of a circle. If the movement of the illumination was against that of the mirror in one meridian and with it in the other, the case was one of myopic astigmatism.

The Physician and the Ophthalmoscope.—Dr. Francis Valk of New York presented this paper. He declared that there were few instruments which were capable of giving such important and reliable diagnostic information as the ophthalmoscope. It was not infrequent for the diagnosis of Bright's disease, to be made first by the results of an ophthalmoscopic examination. Having placed the light in a proper position the observer, should, if possible, keep open the eye not in use. On reflecting the light into the patient's eye, an orange-red reflex from the retina should become visible. If not, then a +6 glass should be brought before the aperture. This should enable one to obtain a clear view if there were no opacity. The beginner found great difficulty in adjusting his eye to the rays of light emanating from the patient's eye. This was most easily accomplished by placing one of the concave lenses—those marked with a red figure—before the aperture. This would neutralize the action for the accommodation of the observer, make the rays of light divergent, and bring the details of the retina into view. If the examination were made upon a young person with a large pupil, it would be found comparatively easy to study the appearance presented by the normal eye. If the pupil were not wide enough, a little cocaine or bromotropine might be dropped into the eye. This would dilate the pupil sufficiently for the examination, and not give the patient any inconvenience after twenty-four hours. Brunettes generally presented a much darker eye-ground than blondes, owing to the greater deposit of pigment. In the region of the macula or yellow spot, found toward the temple, the pigment was somewhat darker. The nerve entrance was readily made out and was of a grayish-white color, and apparently semi-transparent. The retina itself in health could not generally be seen except by an expert. The arteries could be distinguished from the veins by their lighter color and a line along the center.

Incomplete Transverse Congenital Occlusion of the Vagina.—Dr. Samuel M. Brickner of New York presented an abstract of this paper on this subject, reporting four cases in each of which there was an occluding septum found above the hymen. His conclusions were: (1) That transverse vaginal septa were due to an embryonal fold, and (2) that this was due to a return to an ancestral type. He was of the opinion that the fusion of the Müllerian and Wolffian ducts became more intimate at one place, and that then an invagination took place.

Some Scientific and Practical Details Regarding Vaccine and Vaccination.—Dr. Peter H. Bryce, Secretary of the Provincial Board of Health of Ontario, presented this communication. He said that vaccination produced complete protection against smallpox practically in all persons for ten years, and in a large proportion for twenty years. It had been shown by some investigators in Paris that active vaccine lymph could be neutralized by adding to it in test-tubes the serum from vaccinated monkeys, or from human beings recently affected with variola. It was, therefore, a bacterial disease, and it was apparently a fact that the special microorganism had been isolated. It was remarkable that, while the medical profession and the laity generally had accepted the antitoxin treatment of diphtheria, there was still a marked opposition to vaccination. He believed the reason for this was to be found in the fact that vaccination had been made compulsory, and he was of the opinion that if the toxin treatment of diphtheria had been made compulsory the same opposition would have developed.

Reasons for Compulsory Vaccination.—The chief reasons for insisting upon compulsory vaccination were: (1) The theory of the immunity conferred by vaccination was founded on indisputable scientific evidence. (2) The infectiveness of smallpox was uncontrollable, and the experience of every country showed that even the most complete sanitary organization had utterly failed again and again to eradicate smallpox from a community without vaccination. (3) Vaccination was adequate to protect completely against the disease after exposure had taken place, even up to the fourth day, and of reducing the severity of the disease to a non-fatal issue in almost every instance in which the vaccination was concurrent with exposure to the disease.

Vaccine.—The speaker then considered some of the modern vaccine lymphs, and the new rules promulgated concerning their use, and pointed out the necessity for having the manufacture of vaccine lymph under State supervision, or else actually made by State officers. That glycerinated lymph was effective was well shown by the fact that, out of 126,000 vaccinations with this lymph, 98 per cent. were successful. Contrary to modern notions regarding immunity, there was evidence to prove that better protection was given by several simultaneous insertions or scarifications. He firmly believed that the laws should be so framed as to secure the appointment from year to year of properly qualified public vaccinators for every municipality.

Treatment of Purulent Conjunctivitis.—Dr. Edgar S. Thomson of New York read this paper. He said that the first step should be the microscopical examination of the pus to ascertain the variety of microorganism present, yet the treatment should not be delayed on this account. Cases having the appearance of a gonorrhœal inflammation should be promptly treated by the use of a powerful germicide, and for this purpose nitrate of silver was the best agent. The application should be made at the earliest possible moment. If the gonococcus had an opportunity to penetrate the conjunctiva the eye would probably be lost. In babies the result was not apt to be so serious. When the lids were not greatly swollen a two-per-cent solution of nitrate of silver should be applied with a swab to the *entire* conjunctiva, not forgetting the upper cul-de-sac. When the disease was less advanced, stronger solutions might be employed. The abortive treatment should be attempted whenever there was a prospect of success, using a three or four-per-cent. solution of nitrate of silver, and a two-per-cent. solution as a daily application. With the stronger solutions it was well to apply salt solution to neutralize the action of the silver. Protargol was very much less irritating than nitrate of silver, and might be employed as strong as 6 per cent. It was a valuable application in ophthalmia neonatorum when dropped into the eye twice daily. In other forms of purulent conjunctivitis nitrate of silver should not be used, but instead a six-per-cent. solution of protargol. It did not readily stain the conjuctiva. In addition to the above treatment, the eye should be very frequently cleansed with boric-acid solution.

Transportation and the Ophthalmic Referee.—Dr. Justin L. Barnes of New York was the author of this paper. He had addressed a confidential letter to fifty railway companies, and of the thirty-two replies received twenty-one stated that they retained an ophthalmologist for the examination of the eyes of their employees. Apparently at least one-third of the railway companies relied upon lay advice. It was important to test binocular as well as single vision. The reason was obvious; the engineer might have one eye temporarily disabled by a cinder in it, and so might be forced to rely wholly upon the defective

eye. Color blindness might be temporary or permanent, congenital or acquired. A man who had been proved to have a perfect color sense might lose this subsequently, often from the abuse of tobacco. In testing color perception it was very important that the person examined should not be allowed to turn the head from side to side. It was a curious fact that the color-blind person often acquired the ability to distinguish colors merely by the difference of illumination. It was easy to see how an interposed cloud of steam or mist might cause confusion and disaster. It was because of varying degrees of illumination that a man could often pass an examination for color blindness if this were carried out with yard signals, but the ability to distinguish colors in this way was wholly unreliable with changing atmospheric conditions.

Dr. Percy Fridenberg of New York said that the railroad men objected to being examined as to their ability to pick out and match various shades of color on the ground that the conditions were entirely different from those which they met in practice. Moreover, those who could pass the examination with colored wools often failed with the lantern test.

Eye-strain and Headache.— Dr. Lucien Howe of Buffalo presented this paper. The author essayed to give an anatomical explanation of eye-strain, and endeavored to show that it was muscular. He pointed out that recently Helmholz's theory of accommodation had been shown to be in a measure erroneous, and that the act of accommodation was not partly passive, but wholly active. During accommodation the posterior surface of the lens remained the same, and the anterior surface became more convex. This explained the conscious effort associated with looking at a near object. Both the anterior and posterior fibers of the occipitofrontalis muscle were accessories in the act of accommodation, thus explaining the frontal and occipital headache of eye-strain.

Hydrops Tubæ.—Dr. Henry D. Ingraham of Buffalo presented in this paper a report of two cases. He thought the cause in the first case was childbirth and the resulting complications, and in the second case long-standing constipation.

Sterilized Milk, Pasteurized Milk, or Clean Milk.—Dr. C. W. M. Brown of Elmira presented a paper with this title. It was a review of the well-known facts bearing on this subject and was given with the object of emphasizing their importance. The arguments presented were altogether in favor of pasteurization, yet this method required more care and intelligence and more special apparatus, and if not properly done, was apt to be worse than no treatment of the milk. When no ice was available, it was certainly safer to sterilize the milk in summer.

The Examination of Milk by the General Practitioner.— Dr. Henry K. L. Shaw of Albany presented this subject. A scheme was outlined for a rapid, simple, and accurate method of examining either human or cow's milk, and the importance of testing the acidity of the milk was dwelt upon. Milk with an acidity over two-tenths of one per cent. was not fit for drinking purposes. The determination could be made either by a simplified titration method or by the use of Farrington's alkaline test tablets. The next step was to obtain the specific gravity. The author had had a small Quevenne lactometer constructed with a thermometer. This was graduated from 1020 to 1050 and required a little over half an ounce for a reading. Lactometers were standardized at 60° F. and the correct reading could easily be obtained when the temperature of the milk was known. The specific gravity of mother's milk averaged 1030 and it was lowered by an increase in fat and raised by a high percentage of proteid. If the specific gravity of cow's milk was less than the normal (1029 at 60° F.), one of two things might be assumed: either the milk contained an unusual amount of cream or the milk had been watered. If, on the other hand, the specific gravity was higher than normal and the percentage of fat was low, it was fair to assume that the milk had been skimmed. The percentage of fat was obtained in many ways, but the writer preferred the Babcock method. A small hand centrifugal machine had been made for him by O. H. Burrell & Co. of Little Falls, N. Y., which took up very little room and used the regulation size test bottles. This machine could be used for urinary and bacteriological work. The percentage of sugar varied very little and its estimation was not required in an ordinary routine examination. The quantitative Fehling test used for uranalysis could be used.

The total solids of the milk could be determined from the corrected specific gravity and the percentage of fat. The Babcock formula consisted of dividing the specific gravity of the milk by four and adding to this one-fifth the per cent. of fat. This would give the solids not fat, and adding the per cent. of fat to this product the amount of the total solids is obtained.

A sliding milk scale has been recommended by Richmond based on this formula. By it the corrected lactometer reading and total solids could be ascertained at a glance without applying any mathematical formulæ. The amount of proteids could be estimated approximately by subtracting the percentages of fat, sugar, and salts from the total solids. The Hehner and Phloroglucin tests were recommended for the detection of formalin in milk.

Dr. E. E. Smith of New York did not consider that the author's method of estimating the proteids was sufficient. One important difference between mother's milk and cow's milk was in the relative percentages of albumin and casein. When the amount of casein was increased in human milk, certain infantile disorders arose.

Symposium on Hæmatology.—This comprised the following papers:

Blood Examination in General Practice.—Dr. Irving P. Lyon of Buffalo presented this subject in the form of a report of a number of illustrative cases.

The Eosinophiles: Their Etiology and Value in Diagnosis and Prognosis.—Dr. Thomas R. Brown of Baltimore was the author of this paper. In his unavoidable absence, it was read by Dr. Bulkley. He stated that the enormous increase of these cells in splenomyelogenous leukæmia served to differentiate it from the lymphatic form in which they were practically absent. In trichinosis there was a marked increase in the percentage of eosinophiles in the blood, associated with a considerable leucocytosis, and it constituted a valuable diagnostic sign. The increase in the eosinophiles was sometimes of assistance in scarlet fever, tuberculosis, typhoid fever, malaria, chickenpox, smallpox, and other acute infectious diseases.

Degeneration of the Erythrocyte.—Dr. J. C. Da Costa, Jr., of Philadelphia, Pa., presented this paper. He described minutely the microscopic changes observed in this cell. He said that polychromatophilia was a sign of extreme blood impoverishment. The presence of the nucleated erythrocytes of the megaloblastic type was evidence of a severe, though not necessarily fatal, anæmia. He was convinced that they were the prevailing form in every case of pernicious anæmia. Granular punctate basic degeneration was never found in normal blood, and should lead to a careful search for the true cause of the anæmia. The condition had been produced experimentally by the administration of lead, atropine, methylene blue, and other poisons. Clinically, it was constantly found in cases of lead poisoning before the other blood charges were observed, and was sometimes associated with various toxæmias, and the presence of intestinal parasites. It was very frequently present in malaria.

The Iodine Reaction and Its Diagnostic Significance.— Dr. Edwin Allen Locke of Boston, Mass., presented this paper, illustrating it with photomicrographs and lantern slides. A thin film of blood should be spread upon a cover-glass and allowed to dry in the air. It was then mounted on a slide with a drop of the iodine solution, and

examined either immediately or at any convenient time. The examination should be made with an oil immersion lens and a strong illumination, preferably daylight. Normal blood cells exhibited a uniform yellow color. The reaction consisted in the presence of brownish granules in the protoplasm, or a diffuse brownish tint of the cells, or the presence of diffuse brown masses outside of the cells. The latter were usually round or oval. The intercellular reaction was never found in health. The intensity of the reaction in the individual cells seemed to be of as much importance as the number of cells affected. In all doubtful cases, at least 100 white cells should be counted before concluding that the reaction was negative. It was probable that the reaction was dependent upon a change in the cells resulting from toxæmia.

SECOND DAY—WEDNESDAY, JANUARY 28.

The Surgeon's Enemy, the Skin.—Dr. ROBERT H. M. DAWBARN of New York read this paper.

Chemical Shaving.—He advocated the use of chemical shaving in certain cases instead of the razor, and for this purpose recommended Merck's sodium sulphohydrate, a yellow powder. It was best employed in 25 per cent. aqueous solution containing a little glycerin. The hair would be thoroughly removed in ten minutes, and would grow again as quickly as after ordinary shaving.

Mending Rubber Gloves.—For the mending of rubber gloves one should provide a cautery set such as was used for burnt leather work, several test tubes, and two flat-irons. If the end of the finger required to be renewed, the end of the glove finger should be squarely trimmed off, and the tip of the finger from another old glove used as a cap. With the cautery the edges of the rubber should be slightly melted, the patch applied and adjusted by the aid of a test-tube, placed bottom up inside of the glove finger. The patch should be held in place by twine. For mending the flat part of a glove, the flat-irons were used, one as a flat surface, and the other as a weight to hold the patch in place. This method of mending rubber gloves would withstand boiling.

Avoidance of Perspiration in the Operative Field.—The danger of infection from perspiration getting into the wound was dwelt upon, and it was advised that the following method be used to avoid this source of contamination: Some indifferent powder, such as lycopodium, talcum, or stearate of zinc, is mixed with 20 per cent. of alum, and the mixture heated to a temperature which would insure sterilization. One hour before operation the nurse should pour the mixture freely upon the skin, and with a sterile gauze pad should vigorously rub the powder into the skin over the line of the proposed incision and generally over the operative field, and the powder should be left upon the surface. At the time of the operation the powder was washed away, and the usual cleansing applications made. No matter how free the perspiration on other parts of the patient's pody, there would be none over the area treated with the powder during the time necessary for an operation.

The Technique of Prostatectomy.—Dr. RAMÓN GUITÉRAS of New York was the author of this paper. He said that in 1900 he had conceived the idea of taking out the prostate through the urethra after having performed external perineal urethrotomy. Although a search through the literature had led him to think at that time that the operation was original with him and had not been done previously, he had since learned that a surgeon in St. Louis and one in New York City had done the operation. On performing prostatectomy, after having opened the membranous urethra, the tip of the forefinger should be introduced and the prostate separated from the external capsule. The author's curved depressor, an instrument modeled after a urethral sound, was used to hold the prostate, and its curve kept it entirely out of the way of the finger. When one lateral lobe had been freed it could be delivered. The prostate usually came away in two pieces with the so-called middle lobe adherent to one of the lateral lobes. The gland having been removed, artery forceps should be fastened on either side of the incision and the bladder digitally explored to make sure that that viscus was free. After irrigation and the insertion of a perineal drainage tube the artery forceps could be removed; if done before this, great difficulty would be experienced in the introduction of the drainage tube.

Periduodenal Abscess Secondary to Perforative Ulcer of the Duodenum.—Dr. WILLIAM S. BAINBRIDGE of New York presented an abstract of his paper on this subject: He said that there were twenty-two cases on record in which death had occurred without the diagnosis having been made. Two of these had been operated upon, but the diagnosis had not been made until the operation. The author reported one case, with post-mortem examination. Attention was called to the fact that the body temperature of a patient suffering from this condition was usually normal or subnormal until the occurrence of complications. The onset was sudden and accompanied by shock, and there was usually a history of precedent gastric or gastro-intestinal disturbance. The chief symptoms were vomiting, pain, tenderness, and resistance in the epigastrium and right hypochondrium; and constipation.

Dr. LEWIS S. PILCHER of Brooklyn reported briefly his case, and pointed out that although there was an extensive and long-standing ulceration of the duodenum there had been a total absence of symptoms until, in the later stages, the tumor formation had approached the surface.

Dr. H. L. ELSNER of Syracuse, apparently confounding the condition with duodenal ulcer, called attention to the fact that a large number of cases of duodenal ulcer were associated with parenchymatous nephritis, and contended that it was not difficult, in the majority of cases, to make the diagnosis. What difficulty did exist arose from the long intervals without symptoms. He maintained that there was usually a history of the discharge of blood in the stools.

Some Points Regarding the Treatment of the Functional Disorders of the Sexual Organs in the Male.—Dr. FREDERICK R. STURGIS of New York considered in this paper more especially the functional diseases leading to lack of sexual power in the male. In his opinion masturbation was a comparatively infrequent cause, although it played a minor part in the causation of such disorders. A more important cause was "withdrawal" at the time of coition, because the congestion thus produced by erection and copulation was unsatisfied. Another cause was excessive sexual indulgence. He thought that not more than 50 per cent. of these cases were the result of a gonorrhœa which had remained uncured. The physical cause in the gonorrhœal cases was the presence of a urethral stricture, for experience had taught him that by removing the stricture the sexual debility was removed. A similar cause was the presence of granulations in the urethral canal, with or without congestion. The keynote of the successful treatment of these cases was the use of sedatives. Medical men were exceedingly firm in the belief that remedies taken by the mouth were the only things of benefit. His own experience had taught him that this was a most fallacious belief. Medicines given internally were only useful as adjuvants; local remedies were what were required. There was nothing better than nitrate of silver, though the use of sounds and of hot and cold applications were beneficial. The use of sedatives was of far greater advantage than the use of stimulants. Nitrate of silver was more a sedative than an irritant in these cases. With regard to the treatment of sterility there was little to be said, for little could be done. Probably 90 per cent. of the cases of sterility in the male was the result of disease of the epididymis, by which spermatozoa were not allowed to escape, although the usual quantity of semen was ejaculated. Electricity had proved disappointing in his hands, though weak galvanic currents were far better than the faradic current. In the class of

patients under discussion, not only should alcoholic stimulants be interdicted but also coffee.

Dr. R. H. M. Dawbarn of New York thought the medical profession should generally advocate circumcision, not only as a means of preventing venereal disease, but as an aid to sexual weaklings, because of its action in retarding the orgasm. The tying off of a few of the veins at the base of the penis often increased the vigor of the erection. As a not infrequent accident in herniotomies was the division of the vas deferens, it was reassuring to know that Gerster had restored the continuity of this duct and restored its function by using a piece of fine catgut as a mandril and sewing the divided ends of the vas together with fine interrupted silk sutures.

Dr. A. Jacobi of New York was of the opinion that circumcision often proved useful by reason of the profound mental impression it produced. He insisted that masturbation was a powerful cause of sexual impotence, because it weakened self-confidence. In this fact was to be found the key to the treatment of cases of this class.

Dr. Sturgis, in closing the discussion, expressed his belief that masturbation was no more debilitating than natural sexual intercourse indulged in to the same extent.

In Memoriam: Rudolf Virchow.—Dr. Charles A. L. Reed of Cincinnati, Ohio, delivered this address, sketching in an interesting manner the life and work of this great scientist.

Dr. H. Jacobi supplemented this address with a few remarks on Virchow's penchant toward America and American students and physicians.

President's Address: Progress, Unity, Liberty.—Dr. Henry R. Hopkins of Buffalo delivered this address. He said that unity in medicine was absolutely essential to progress in State medicine, the supreme function of our profession. Satisfactory progress in this field could only obtain in this country through the establishment in the Cabinet at Washington of a Secretary of Health. It was well to bear in mind that medical unity would never be made easier by dwelling upon the limitations or imperfections in the practice of our brethren. The most important event in the history of the medical profession in the past half century was the inauguration of the system of State license for the practice of the healing art. Our best thought and endeavor should be given to the extension of this beneficent system. There were unfortunately at present three examining boards in this State, and the responsibility for this cumbersome legal machinery rested primarily upon this society; yet it was within our power, and, the speaker thought, was our bounden duty, to sweep away this incongruity and secure unity in form as well as unity in spirit. The twentieth century saw empiricism fading and modern scientific medicine auspiciously inaugurated.

Plasmodiophora Brassicæ.—Dr. Harvey R. Gaylord of Buffalo was the author of this paper. Certain forms of this organism, he said, presented an appearance so closely resembling tissue cells that it became difficult to differentiate it from them. It shared with many of the protozoa the property of being blackened by osmic acid, making it likely to be mistaken for fat.

Primary Carcinoma of the Vermiform Appendix.—Dr. Arthur W. Elting of Albany was the author of this paper. He said that he had collected from the literature forty cases, of which eight were probably not true primary carcinoma. Three recent cases, studied by Dr. Elting, were reported. It was pointed out that, theoretically, the appendix should be frequently the seat of carcinoma. One of the reasons for expecting its more frequent occurrence here was that carcinoma was a common sequel of chronic inflammation. As several of these carcinomata of the appendix had been accidentally discovered at autopsy, there having been no symptoms pointing to such disease, there was reason to believe that many cases were overlooked. The chief symptom was pain in the region of the appendix. Primary carcinoma showed a tendency to development in early life, but no disposition to extension or metastasis.

Symposium on Arteriosclerosis.—This comprised the following papers:

The Early Recognition and Symptoms of Arteriosclerosis.—Dr. Delancey Rochester of Buffalo presented this paper: The cases could be roughly classified thus: (1) Those due to strain of occupation; (2) those the result of the introduction into the system of poisons from without, *e. g.* syphilis, lead, and alcohol, and (3) those cases dependent upon poisons arising from within as a result of faulty metabolism. The interference with the blood supply gave rise to perversions of function, *e. g.* constipation and indigestion, both gastric and intestinal. In many cases the disease began in the capillaries, and hence hypertrophy of the heart was present early, and could be appreciated by a careful study of the pulse, using three fingers and varying pressure to determine the arterial tension.

Arteriosclerosis and the Heart.—Dr. Glentworth R. Butler of Brooklyn read this paper. He said that the cases in which the heart was affected in arteriosclerosis naturally fell into two groups depending on whether or not the coronary arteries were involved in the sclerotic process. Cardiac hypertrophy was not a necessary result of arteriosclerosis. In the senile form the heart was frequently not enlarged or the arterial tension increased. Arteriosclerotic hypertrophy reached its highest degree in middle age, though it was sometimes observed in quite young and robust men. In the course of time the simple hypertrophy gave place to dilatation and a train of symptoms which were difficult to distinguish from those of ordinary organic heart disease. These persons were apt to present a sallow, pallid face, enlarged venous radicles, a wet skin, a weak pulse when compared with the apex beat, and a distinct loss of strength. In quite advanced cases anginal attacks with an irregular, weak, and slow pulse were rather characteristic. True angina pectoris was, however, a rather rare symptom, and was almost invariably dependent upon a sclerotic process in the coronary arteries and myocardium. The speaker said experience had taught him to be suspicious of cases presenting marked or painful gastric attacks, occurring in elderly persons showing myocardial and arterial degeneration.

Arteriosclerosis and the Kidney.—Dr. Irving P. Lyon of Buffalo was the author of this paper. Syphilis, alcoholism, plumbism, gout, and prolonged physical strain were laid down as the important etiological factors. The first step should be to determine the primary seat of the disease.

Arteriosclerosis and the Digestive System.—Dr. Charles G. Stockton of Buffalo presented this paper. He dwelt upon the possibility of gastric ulcer arising from this cause, and advised caution in ascribing abdominal disease to arteriosclerosis. Of course, when it was evident that the arterial supply was greatly diminished as a result of vascular disease, such an assumption might be warranted. However, arteriosclerosis was indirectly a common cause of digestive disturbance. Among the direct effects on the digestive apparatus was the somewhat unusual one of intense abdominal pain, generally referred to the "pit" of the stomach, and closely resembling gastralgia. The opinion was gaining ground that arteriosclerosis was more often a direct cause of gastric disease than had been hitherto held.

Arteriosclerosis and the Nervous System.—Dr. William Browning of Brooklyn discussed this aspect of the subject. He enumerated a large variety of symptoms that might be found in a great many other conditions also, and very properly observed that skill and experience were necessary to interpret aright this diverse symptomatology.

Arteriosclerosis and Mental Disease.—Dr. Adolf Meyer of New York presented this subject. He believed that the frequency of mental disease attributable to dis-

ease of the kidney was ordinarily exaggerated. Arteriosclerosis of the heart and aorta was exceedingly frequent in the insane, but it was not often that mental disorders could be directly ascribed to these affections. This could could only be done in cases of arteriosclerosis of the brain itself, and even here many difficulties were encountered. Arteriosclerosis of the brain was often associated with loss of memory of the immediate past and transitory delirium or mental confusion Sometimes these persons were guilty of setting fire to houses, stealing, or sexual misconduct. Mental disease, occurring at that period of life in which arteriosclerosis was most common, showed no differences in its nature and course that could not be fairly accounted for by the diminished resistance of later life. In short, there was no justification for speaking of arteriosclerotic insanity, though it was possible to recognize clinically senile and pre-senile involution. Naturally enough, then, there was no special treatment for cases in which the underlying condition was arteriosclerosis. The knowledge of the existence of this element in a case was chiefly of value in prognosis.

Pulsus Infrequens.—Dr. Thomas E. Satterthwaite presented this paper. He thought it was unfortunate to designate the condition by words having the termination "cardia," for this tended to lead one away from the main feature, the pulse, to the heart. For this reason he preferred the term *pulsus infrequens*. By general consent a pulse below 60 was regarded as "infrequent." According to his experience, the infrequent pulse was most often seen at or about the middle period of life and was five times more frequent in the male. The infrequent pulse was of two varieties, viz.: (1) physiological and (2) pathological. There were two well-known varieties of the first—the infrequent pulse of inheritance and the slow pulse of pregnancy. The pathologically infrequent pulse was subdivided into: (*a*) the paroxysmal, periodic, or temporary variety and (*b*) the chronic variety. The latter was uncommon. The physiological variety gave rise to no untoward symptoms—indeed, an increase in the pulse rate often caused discomfort. There was a group of cases that appeared to be dependent upon gastrointestinal irritation. As the physiological and paroxysmal forms were thought to represent 80 per cent. of all cases of infrequent pulse, it was evident that the prognosis was, on the whole, favorable. The prognosis was not so good in the chronic form. Experience had shown that medicinal treatment, having for its object an increase in the frequency of the pulse, was invariably harmful. Even alcoholic stimulants should be used with caution. The infrequent pulse alone should not be treated, but rather the underlying condition. The first point to determine was whether the pulse was of the physiological or pathological variety and whether the pulse was intermittent or deficient. The author commented upon the relation of his cases to mitral disease, especially stenosis, arteriosclerosis, brain disorder, diabetes and chronic nephritis, and pointed out the danger of giving digitalis in the large doses often used in our hospitals and the fact that milder cardiac remedies, to the almost total exclusion of digitalis or its congeners, might alone, or in conjunction with hydrotherapy, resistance exercises, massage, electricity, and compressed air, be effective remedies.

Dr. E. Libman of New York said that there could be no doubt that obstruction to the circulation caused arteriosclerosis. Atheroma was not infrequent in young persons. It was important to examine the arteries of both the upper and lower extremities when making the diagnosis of arteriosclerosis. There might be extensive calcification of the peripheral arteries without any involvement of the aorta proper. It was probably within the experience of many, that pulmonary œdema developed in persons exhibiting arteriosclerosis without other assignable cause. Disease of the vessels of the lower extremities had been noticed in the lower extremities of persons between thirty and forty years of age, especially among Russian and Polish Jews. The lesion was usually an obliterating endarteritis with thrombosis above or below the point of narrowing of the vessel. In connection with the occurrence of infections in those having arteriosclerosis it should be remembered that these persons are peculiarly susceptible to the development of systemic infections. They were especially liable to acute endocarditis, and the thickened valve here was just as much a point of least resistance as in acute rheumatism.

Dr. A. L. Benedict of Buffalo said, with regard to the use of hot-air baths in cases of arteriosclerosis, that of course anything which would exercise the arteries and change the arterial tension was contraindicated, but in the earlier stages baths were useful. He was of the opinion that, in connection with hepatic sclerosis, too much attention had been paid to alcohol as a causal factor, and that arteriosclerotic changes had a great deal to do with hepatic cirrhosis.

Dr. Edward D. Fisher of New York said that in syphilis there was not an ordinary and general endarteritis but one affecting exclusively or specially the vessels of the nervous system. This gave rise to thrombosis and hemorrhages in the brain and to disease of the vessels in the spinal cord, thus causing mixed spinal paralyses. In cases of apoplexy occurring in comparatively young persons the cause was probably a disease affecting the muscular coat of the arteries.

Dr. Henry L. Elsner of Syracuse reported an interesting case in which the Stokes-Adams' phenomenon had been present to a very marked degree. In doubtful cases of vascular disease the sphygmograph should be called to our aid. In the cases of erythromylalgia that he had reported there had been found far-reaching changes in the peripheral vessels.

Dr. Stewart of Elmira reported a case of severe gastralgia of twenty years' standing that had terminated in a fatal attack of angina pectoris.

Dr. J. J. Walsh of New York referred to the influence of heredity and instanced the fact that where whole families succumbed at a comparatively early age, careful observation in early life usually showed the presence of arteriosclerosis. He also reported an interesting case of pulsus infrequens occurring in a theatrical dancer. Although her pulse rate was never over 30, it gave rise to no discomfort and did not interfere with her rather arduous duties. Apparently the condition had been acquired, for although she had suffered from all of the usual diseases of childhood no physician had made any comment upon the pulse, and the existence of this slow pulse had not been noted until after an attack of the grip.

Dr. Satterthwaite said that arteriosclerosis was by no means always general; it was sometimes confined to the Sylvian artery at the base of the brain. The iodides should be given persistently for months and years and would do good in the mild cases.

Some Points Pertaining to the Therapeutic Management of the Uræmic State.—Dr. Heinrich Stern of New York read this paper. He said that the diversity of opinion in regard to the various procedures and medicinal agents in the treatment of uræmia could be attributed only to insufficient consideration of the original affection, on the basis of which uræmia had been produced. Uræmia was not the result of one and the same causative factor in every instance; the serum of each variety exhibited some special features. This diversity might be due to the different underlying renal condition, to the specific material of infectious diseases, and to the decomposition products of the retained substances.

In the large white kidney the outflow of water was seriously hampered; in the sclerotic kidney this was not the case. The tendency to convulsions in parenchymatous, and to coma in interstitial, nephritis seemed to be caused

by the varying constitution and physico-electric condition of the respective blood sera.

The large quantities of retention nitrogen in the serum of chronic interstitial nephritis apparently stood in causal relationship to the natural termination of this disease—uræmia.

In chronic parenchymatous nephritis uræmia did not occur so often and was not so grave. *Sweating* was indicated under certain restrictions in every instance of acute uræmia, and should be employed soon after the onset of the attack. Its action was more beneficial and lasting in uræmia dependent on chronic parenchymatous nephritis. By free sweating, large amounts of catabolic substances were eliminated from the blood serum. Enteroclysis or hypodermoclysis might be employed in conjunction with sweating if this were continued for some time. *Venesection* produced the most lasting results in cases following acute nephritic conditions. In children, the usual amount abstracted varied between 100 and 250 c.c.; in adults, 300, 400, and even 500 c.c. might be abstracted. The good effects could be ascribed to the abstraction of a few hundred cubic centimeters of blood and a corresponding amount of retention material. Withdrawal of blood did not alter the molecular concentration of the remaining blood, and did not increase the electrical conductivity of the blood serum. Oxidation was also not augmented. The improvement following venesection seemed to be due to the relief of vasoconstriction in the kidneys, or central nervous system, or in both. The effect of hypodermoclysis and infusion were of a more or less transitory character, but might endure sufficiently long to bridge over a critical phase in the uræmic attack. Isotonic solutions of chloride of sodium were not so good in uræmia as hypotonic solutions; hence a 0.5 per cent., or 0.6 per cent., solution sufficed. These agents were of special value in acute renal conditions and in chronic parenchymatous nephritis. While morphine in small doses was innocuous in the uræmia of acute renal disease and chronic parenchymatous nephritis, and might possibly help to control the convulsive manifestations, it was not indicated in the uræmia of chronic interstitial nephritis, in which convulsions hardly ever appeared, and might even do harm.

Hepatic Ballottement or Bimanual Palpation.—Dr. A. L. Benedict of Buffalo substituted for the reading of this paper a demonstration of the method. By making pressure downward, forward, and to the left, both hands were made available for palpation, with the additional advantage afforded by the greater ease with which a moving body could be felt and outlined.

THIRD DAY—JANUARY 29.

Cancer of the Cervix Uteri Treated by the X-ray.—Dr. Thomas S. Scully read this paper. The method employed was to use an elongated *x*-ray tube capable of being inserted into either vagina or rectum. The treatment was given for fifteen minutes or more on alternate days. Three cases were reported in which the results had been encouraging.

An Operation for Cicatricial Contractures of the Upper Extremities.—Dr. A. H. Traver of Albany described the method he had successfully employed in a case of extensive cicatricial contraction rendering the arm practically useless. The cicatrices were divided and a series of four operations with "sling" flaps constituted the treatment.

Officers Elected.—*President*, Dr. A. T. Bristow of Brooklyn; *Vice-President*, Dr. Edward B. Angell of Rochester; *Secretary*, Dr. L. C. Curtis of Albany; *Treasurer*, Dr. O. D. Ball.

First Mention of Surgeons in the British Army.—The first mention of surgeons in the British Army was in 1223. Edward I. had a paid surgeon accompanying his army in Scotland in 1296.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 24, 1903:

	Cases.	Deaths.
Measles	158	7
Diphtheria and croup	391	46
Scarlet fever	250	17
Smallpox	1	..
Varicella	99	..
Tuberculosis	285	168
Typhoid fever	59	5
Cerebrospinal meningitis	..	..

Health Report.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ending January 24, 1903:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS
California, San Francisco	Dec. 28–Jan. 11	10	..
Colorado, Denver	Jan. 3–10	7	..
District of Columbia, Washington	Jan. 10–17	2	..
Illinois, Chicago	Jan. 10–17	14	..
Indiana, Evansville	Jan. 10–17	3	two imported, 1 on river steamer.
South Bend	Jan. 10–17	5	..

THEORY AND PRACTICE OF SPINAL COCAINIZATION.

BY G. K. DICKINSON, M.D.,
JERSEY CITY, N. J.

THE history of spinal cocainization reveals a phase of mind in the medical profession not dissimilar to that prevalent at the time of the attempted introduction of general anæsthesia, in fact, of any other new truth. Corning, in 1885, after a series of experiments on animals, proving the effect of cocaine thrown in the neighborhood of the cord, remarks: "Whether the method will ever find an application as a substitute for etherization in genitourinary or other branches of surgery, further experience alone can show. Be the destiny of the observation what it may, it has seemed to me, on the whole, worth recording." This modest statement epitomizes the results of a series of laboratory experiments made by a man possessing a competent knowledge of physiological anatomy and the effect of this drug. His observations were unnoticed and his prediction remained unverified until Bier, in 1899, fifteen years later, published an article recommending the same in genitourinary work. Tuffier, in the same year, extended its application to operations on the lower part of the body. To both of these surgeons is due the credit of having worked out the technique of the day. The former, more conservative and less confident, has done much to induce the present fear of misfortune. Tuffier, with perhaps a keener insight, has kept the method in its proper place as to the profession, and though it is and will be for a few years in an experimental stage, yet it has a *raison d'être*. As Corning has remarked, apparently "spasmodic hardihood, defective technique," and I may add, careless methods of sterilization and selection of the cocaine have tended to a gradual loss of confidence in the procedure. In order better to comprehend the advantages and limitations of this method of analgesia, it will be necessary to study in detail the anatomy, physiology, and practical application of the same.

The structures overlaying the spine in the lumbar region, through which the subarachnoid space is entered, are skin, muscle, considerably mixed with the apponeurotic fibers, and more or less fat. The skin may be dimpled at the spine line, perhaps elevated as it runs over the prominent spines. The fibrous tissues are frequently condensed at the bone, and are sometimes so firm as to deceive the tyro and produce, when the needle is pushed through it, a feeling as though bone had been reached. If this condition is extreme, some doubt may prevail as to whether the canal has been entered or not. At times the depth of fat is sufficient to make the distance to the canal greater than the length of the needle, and some ingenuity is required to make an entrance at the first attempt, particularly if the spine landmarks are not found.

Extending from one articular process to the other is an interval of about a quarter of an inch, in which is the ligament subflava. The dimensions of this space is modified somewhat by position, so that on bending forward and to the left, the space on the right side is moderately increased in size. Between the laminæ the ligament contains an excess of yellow elastic tissue. Nearer the transverse processes this tissue is deficient and the tougher white tissue is more abundant. A needle pushed through the ligamentum subflavum at its middle or near the spine line will meet with temporary resistance, only followed by a quick progress of the point as the intraspinal membranes are entered, the latter not possessing any sense of resistance. If the needle enter near the transverse processes, the sense of touch will be as though no membrane was encountered and passed, but the pedicles of the spine will be reached without fluid being exuded. The needle being pushed to its limit and bone found, though the operator knows from experience that the canal has been entered, is now gently withdrawn and a little clear fluid will flow.

The medulla ends at the lower level of the first lumbar vertebra. From this descend the cauda equina, the filum terminale, and the conus medullaris. The nerves forming the cauda equina are structurally the same as the nerves outside of the canal. The ganglions of the sensory roots are at variable distances from the medulla, some lower than the point selected for injection. The nerves forming the cauda seem to be bunched with constant uniformity, capillaries and lymphatics running between them and surrounded by a venus plexus. The cauda is held in position by the membranes. The distance from the ligamentum-subflavum to the nerves composing the cauda equina varies, but if the sensation of pain or distress in one or the other foot can be taken as a guide, in the mesial line there is at least a quarter of an inch of fluid. The penetrating needle does not enter the canal in the same direction each time. Though the effort is to pass from a point hypothetically constant, yet on account of the fact that the one anatomical guide, the spinous process, being so variable, in shape, and the depth to the ligamentum-subflavum being so inconstant, the needle will often be misdirected and pass over to the left side, perforating the ligament just under the spinous process. At other times it will enter well toward the right transverse process. In the former the needle will transverse some distance before the cauda equina can be punctured, and at the latter point of entrance it may more easily be touched. Pricking of the cauda equina is inferred by complaint of pain, either in one foot or the other, each having been observed. Also by an excess of blocking of the function of the nerves of the side invaded, and a more prolonged effect of the cocaine in that limb. As Corning has shown in his physiological experiments that cocaine thrown into the veins outside of the cord will be drawn into it and produce an effect even sufficient for the production of paranalgesia, but not so positive nor so certain as the same drug thrown into the subarachnoid space.

The effect produced will depend on several factors, anatomical and physiological. The fluid in the subarachnoid space is variously stated by our writers to amount to over a half an ounce or two ounces. This fills the subarachnoid space in the spinal cord and the ventricles of the brain, the two cavities being connected by the foramen of Magendie. According to several authorities, this foramen is not always patent, and it is a fair presumption, though not mentioned, that at times the foramen is not sufficiently patent to permit of a free flow of fluid through it. The motion of the spinal fluid is produced in part by respiration and partly by motion of the body, so that cocaine sent into the subarachnoid space cannot reach the fourth ventricle and the base of the brain, except this foramen be sufficiently patent to allow passage by the motion induced by respiration and osmosis. Experiments on dogs have shown that in them a pigment in the fluid thrown into the canal at the lumbar level will paint the base of the brain in thirty seconds. This may be accepted in that animal, but it does not prove that cocaine can be so quickly distributed to the important structures at the base of the brain; and the medulla in sufficient potency to produce a physiological toxic effect. Clinical experience has not as yet proved it.

Cocaine, first put on the market in 1884, has perplexed the commercial chemists, as have other substances, such as bismuth, chloral, and antitoxin of diphtheria. Each one of these medicaments was introduced to the profession before the product used was in a state of purity sufficient to the obtaining of a uniform and reliable effect. Commercial cocaine is a difficult alkaloid to obtain chemically pure and particularly to separate from isoatropyl cocaine, a cardiac depressant of great potency, and undoubtedly the cause of the numerous deaths ascribed to cocaine in the early days of its use. At the present time care must be taken in the selection of the article used, to prevent mishap and the subsequent distrust of the drug. Pure cocaine, free from any adulterant, is safe in proper doses, and can be relied upon to have a uniform effect, being an ether base, it is rapid in its action, both local and systemic. The local effect begins at once and reaches its full intensity in a few minutes. This effect is the sole one until such time as the salt enters the circulation by the veins and produces its secondary systemic effect. Distribution by means of the fluid in the subarachnoid space is possible and presumably effected to some extent, but the circulation of the subdural fluid is not an organic one and, depending on respiration and body motion, must be slow and uncertain. Osmosis also is an unsatisfactory explanation of possible effects on the medulla and higher centers. The fact that pigments do reach the base of the brain in thirty seconds cannot mean that this salt will do so in sufficient strength to paralyze the centers there. The local effect is in from three to five minutes to produce a complete analgesia of the superficial nerves of that part of the body below the point of puncture. In five minutes more the deeper nerves are affected in the same way. The strength of the intraspinal solution of the drug diminishes as it spreads through the space and with the rapidity of its intravascular absorption, so that as the primary analgesia extends upward it becomes surgically more uncertain, and though sometimes complete cannot be counted upon. At the mammary line it generally stops so far as surgical procedures are concerned. After twenty minutes have expired from the time of puncture systemic results may be expected. Being in the dose ordinarily used ($\frac{1}{2}$ grain) a vasomotor stimulant, the skin blanches, the cerebrum becomes anæmic, and vomiting results; in the act of vomiting the anus, being relaxed and lacking in apprehension, fails to contract and involuntary defecation may result. In some fibrillary contraction of the muscles and mild intoxication may ensue. Some authors claim that the kidneys are not affected by a therapeutic dose of cocaine, though animal experimentation shows that in toxic doses suppression occurs.

This analgesia is progressive and at times irregular in primary manifestation, showing first in the pudendal region, at other times in the feet. Areas of analgesia coalesce until the complete effect is produced. If cutaneous sensibility is complete, deep sensation is also complete. Manipulation of the omentum, being felt as an obscure ache in the abdomen, even when the superficial nerves are completely affected. If the cocaine pass to the medulla and there is not sufficient dilution or absorption in the meantime, an effect may be produced on the centers, in the medulla, producing cardiorespiratory effects of panting and rapid heart action with a sense of suffocation. These latter phenomena have never been noticed by the writer in the least degree, with the half-grain injection, but as this procedure is in its infancy, it has been watched for, and no patient is allowed to be left without an attendant for two hours after puncture. Sometimes the respiration is accelerated, but not sufficient to be noticed by the patient as a distress. The heat center, either by a local effect or by the drug acting after absorption, is affected, and by increased metabolism the temperature as read in the rectum may rise from one to five degrees. Some complain of a headache, and at times it is severe, general, and not easily relieved.

A more constant effect is a severe ache in the back and thigh. This comes on soon after the analgesia effect has worn off, and persists for several hours, particularly in those having previously suffered from the same pain, as a uterine neurosis.

The method of lumbar puncture is an art, and to be uniformly successful experience is necessary. The surgeon attempting this for the first time will often make several attempts before he will succeed, and perhaps then in the end fail. Conditions may exist to prevent absolutely a successful accomplishment, such as ossification of the ligamentum subflavum or hyperostosis of the lamina.

These complications are rare, and it may be taken as an established fact that if entrance is not made the fault is that of the operator. The skin of the back and loin should be prepared as carefully as before an abdominal operation, so that free manipulation of the back and a proper search for the spinous processes made. The spinous process is the guide, and if this is not found, further effort is in the dark. Then, again, if the spine is not properly estimated as to its size or the position of its lowermost point, the point of entrance will not be rightly located. A good plan is to have the patient sit well bowed forward with the bend at the lumbar region and with the forefinger of the left hand supported by the thumb pressed against its pulp, push the nail of the forefinger repeatedly up and under the spine to be located. By doing this the parts are pressed in and the undermost part of the spine found. (Ordinary pressure on the spine does not find the lower edge, but the lowermost prominent point.) Finding the lower limit of the spine selected, generally the third, take a point a little less than a quarter of an inch below and a half inch to the right for the point of entrance of the needle. As the only sensitive tissue is the skin, this can be

frozen with a spray of ethyl-chloride and a puncture made with a bistoury. This will also prevent the possible pushing in of skin microbes.

This being done, the needle is introduced through the wound, pointing to "five o'clock," directing the point a little upward and toward the ligamentum subflavium.

Generally the needle will enter jumping through the ligamentum subflavum with a sense easily appreciated by the finger. If the needle pass a little too far to the right, the fibrous tissue near the transverse process will be punctured and a sense of continuous interference felt and, perhaps, no fluid flow. Once in the canal, fluid generally comes, but at times it must be started by a cough or straining effort. The spinal fluid will, at times, rush out in a steady stream an inch from the end of the needle, though generally it comes in drops. This fluid is always clear and limpid. In the earlier operations no fluid was allowed, if possible, to escape, but of late an effort has been made in the other direction, and about twice the amount was allowed to escape as thrown in. Over the puncture a sterile gauze should be applied and maintained by adhesive strips.

The possibilities of harm present or remote arising from the use of the procedure under examination is suggested by the known physiological action of the drug in the laboratory, and from the experience obtained by the observant surgeon. The latter is the only sure test, but requires years of careful and unprejudiced work. The over-enthusiastic, as well as the timid, who do not possess the proper knowledge of pathology and physiology may not read their results clearly and give the procedure the proper place in the techniques of the day. The problem is not alone cocaine, but cocaine plus the lesion operated for and the physical state incident to the time.

Cardiorespiratory phenomena are the dangers to be apprehended in the main, and if it can be shown in time that the risk is sufficiently minimized it will prove the true value of the method. The possibilities of a blocking of the centers in the medulla are certain if large doses are given, but can half a grain even in any person, an adult, suffice to induce alarming symptoms? As yet the opinions of the different reporters vary, as is common when a new method is introduced. Speaking for myself, of work done at Christ Hospital in a series of over 200 cases, no anxiety need be felt. Not once has there been any distress to a patient from dyspnœa or palpitation. The blanching of the skin and consequent nausea have been observed at times with vomiting in a few cases shortly after the puncture, or later when disturbed by being transferred to the bed. In the earlier cases, when but few drops of the spinal fluid was lost, or perhaps due to faulty choice of cocaine, the nausea and vomiting was more frequent and persistent, but in the last 135, with a removal of the same quantity thrown in, this phenomena has been reduced to such a minimum as to be quite unusual.

Danger of infection of the cord is an idle one to a careful surgeon accustomed to careful sterilization of instruments and skin, when the cocaine has been properly sterilized. A temperature above 180° will more or less rapidly destroy the drug producing the innocuous ecgonine. To sterilize a solution without destroying it, a plan suggested to and carefully carried out by Van Horne of New York is to make a two-per-cent. solution in sterilized water and put 25 minims into small glass capsules. This is exposed to a temperature of 176° for four hours for four successive days. A procedure of this kind renders the solution safe surgically and does not influence the drug effect. Suppression of urine has been observed in animal experimentation, but is hardly probable in the dose usually given.

The most concern must be felt from the conditions known as idiosyncrasy. A case of ether suppression of urine in a woman who had but a cervix to be repaired and who had but an ounce administered by the closed method led to this investigation of cocaine spinal analgesia. In this case the epithelia lining the tubules had all exploded. Not alone to ether do we find idiosyncrasies, but to many other drugs as well as common articles of diet. The test is in their relative frequency. Cocaine analgesia is to be preferred to ether in all cases when the patient will not be over-much mentally disturbed by the time and surroundings. No meals are lost, no metabolic changes are induced; contentment and a serene mind make for a speedy convalescence. The claim is that this procedure is not empirical, but based on clear physiological grounds that the action of the drug is not uncertain if pure, and that, in regulated doses, its action can be predicted with much certainty; but nevertheless many more cases must be carefully observed before it can be rated with ether and chloroform in safety. It is not proven to carry enough risk to prohibit careful clinical experimentation.

On the one side we have a busy and perhaps distracted operator trusting his anæsthesia to a young interne learning the art with the ordinary risks of the ether or chloroform and the added ones of the tyro, on the other hand is a local anæsthetic given by the surgeon himself. All cases of general anæsthesia are watched for some time after the anæsthesia has ceased, certainly until the patients can do for themselves, and certainly all cases of spinal analgesia must be watched, for possible chance of cardiorespiratory failure has passed. Until at least 100,000 cases have been observed and properly recorded it will be idle to condemn or laud this method.

Surgical analgesia of the lower limbs will be attained in three or five minutes in the great majority of the cases, but for operations on the mammal or head at least thirty minutes must elapse. The writer has not yet experimented with cocaine thrown in other regions as to the ability to obtain a similar result, and perhaps if such effort were made it might be found successful. With few exceptions all operations may be performed with comfort to the patient and no disturbance to the operator.

278 Montgomery Street.

Treatment of the Pains in Locomotor Ataxia.—Given Campbell finds that the chloride of aluminum, first recommended by Gowers, gives absolute relief from the fulgurant pains in locomotor ataxia. The pains are usually controlled before the dose reaches 5 centigrams, or ½ gr. This dose, administered three times a day, largely diluted, after meals, has been given by the author to a number of patients for periods varying from a year to less with absolutely no disturbance of the digestion, or of the general health. On the contrary, the immunity from the pains has enabled them greatly to improve in general health, and this improvement has reacted favorably on the other symptoms of the disease. A result such as this, attained without the use of narcotics or heart depressing analgesics, and with a certainty that amounts almost to specificity, is well worthy of a trial, especially in a class of patients who, in addition to these pains, have much to make their lives miserable.—*St. Louis Medical Review.*

ESSENTIAL AND PAROXYSMAL TACHYCARDIA.*

By J. J. MORRISSEY, A.M., M.D.
NEW YORK.
VISITING PHYSICIAN, ST. JOSEPH'S HOSPITAL AND ST. VINCENT'S O. P. D.

It may be well, at the outset, to define tachycardia not as simple "heart hurry," but as a species of rapid heart, depending upon causes within the heart itself, or produced by other causes more or less removed from the cardiac region. There are certain peculiarities which distinguish true tachycardia from the evanescent "heart hurry" so frequently produced by the most trivial causes. (1) The attack is sudden in its onset, reaching its height almost immediately. (2) The patient may or may not be entirely unconscious of the great degree of palpitation. (3) There is generally a definite period covered by the attack. (4) The reversion to the normal condition is as sudden as the onset, the vestiges of the storm through which the patient has passed rapidly disappearing. Let me add, further, that the main characteristic of tachycardia is the tendency to paroxysmal and recurrent attacks of palpitation, during which there may be great mental distress, prostration, and dyspnœa, with periods of intermission between the paroxysms, in which the pulse-rate is normal. The temperature is slightly raised during the attack, and with some individuals it appears to be constantly higher than in the normal condition.

I do not regard the temperature elevation as of any special significance in tachycardia, any more than in any other condition in which there is a decided disturbance of the relations existing between the organs. The attacks may persist for years with slight or prolonged intermissions. In some few cases they may follow the slightest subjective disturbance; in others they occur only when great mental agitation upsets the equilibrium of the system. We notice in the heart itself, during the attack, a decided accentuation of the cardiac sounds, and the presence of murmurs which rapidly disappear with the culmination of the disturbance. The action of the heart may be regular, or arrhythmia may be present during the seizure. The cardiac dulness is measurably increased, acute dilatation rapidly supervening upon the beginning of an attack, and as quickly disappearing upon recovery. Tachycardia, from being intermittent, may become continuous, and its persistency result in all the symptoms of advanced dilatation, dyspnœa, orthopnœa, dropsy, and, frequently, apoplectic seizures. When these signs and symptoms of advanced heart disease occur, the question arises as to whether interference with the functions of the heart did not already exist from disease well established. It is at times difficult for even the most astute diagnostician to ascertain the absolute amount of mischief produced by cardiac disease. The heart of the individual patient, even when diseased, has to bear the stress of many trials ere we can accurately judge of its power to cope successfully with difficult situations. Two hearts may be clinically alike, which pathologically are entirely different. So that attacks of tachycardia may precipitate in some hearts all the consequences of advanced disease, while in another, in which structural degeneration has not taken place, the burden is lightly borne.

From a report of the histories given, tachycardia, as to time, may be classified as "short" and "long." The first is accompanied with vertigo, epigastric distress, and, at times, a sensation of cardiac expansion. There is no discoverable cause, and the symptoms are mainly subjective in character, with the exception of a slight bruit, which it is oftentimes difficult to localize, and a vibration of the chest wall felt on palpitation. The pulse rate at once ascends to two hundred or more; it is not a gradual ascension, as if some slight interference with the inhibitory power of the heart was taking place, but rises immediately, while the resumption of the normal heart beat may take place more slowly, the subjective symptoms quickly disappearing.

The long attack may cover a period of days, to the great distress of the patient, who may suffer seriously from the aggravated symptoms of cardiac failure, as dyspnœa, cyanosis, and a feeling of impending death, similar to angina pectoris, minus the sense of constriction so bitterly complained of in the latter disease. Percussion demonstrates the presence of considerable cardiac dilatation. The long attack may result in death.

Out of the eleven cases collected by Bouveret, four died during the prolonged attack. In the remissions the patients suffer very slightly, though the fear of an impending attack is constantly before them. The weak and the strong, the feeble and the robust, those who are engaged in mental occupation as well as the more arduous labors of the shop and the factory, are liable to suffer from this affection.

It is found more commonly between the ages of twenty and forty years, and attacks about equally both sexes. That it is also seen in very advanced years, the following case will illustrate:

M. B., a woman seventy years of age, came to my clinic complaining of "heart disease." She was of medium height, and of excellent appearance for her years. Her family and personal history were negative, except as to the condition of her heart. She had always been active and energetic in her household cares, and was able to accomplish much, except when her "heart began to beat fast," then she became confused, weak, dyspnœic, and finally so exhausted that she was compelled to remain in bed for a day before feeling sufficiently safe to resume her domestic duties. Not all attacks were of this aggravated character. At intervals of ten days or so, she had suffered from slight attacks, which resulted in her retirement for an hour; assuming the recumbent position appeared to shorten the attack. She fully realized when the attack was coming on, by a feeling of numbness in the cardiac region—the calm preceding the storm—and then, with almost cyclonic force, her heart rapidly cleared itself, as it were, from its moorings, and began to palpitate with inordinate vigor. The attacks of dyspnœa had no special connection with the tachycardia, as frequently she had to rest upon the street, but they were aggravated when the palpitation had lasted for a number of minutes. The attacks ceased almost as suddenly as they began, leaving her prostrated.

The pulse was about 80, feeble, intermittent, and irregular in character. There was marked sclerosis present. While listening to the heart's action, I suddenly heard it rebound, and then rapidly its pulsations increased. The patient asked to be seated. Her pulse was 150, so far as could be counted, a condition of delirium cordis preventing accuracy. Her eyes were staring, her face cyanosed, the peculiarly purplish condition of the lips demanding attention, while the perspiration was clearly seen on the forehead. She with difficulty asked for brandy, but before its administration I felt the pulse stop, and then, after a few seconds, resume its normal rate, the cyanotic hue at the same time disappearing. She was able to leave the building

*Read before the Manhattan Clinical Society.

within an hour, though the prostration subsequently to the attack appeared extreme. In this woman's heart a condition, presumably of fatty or fibroid degeneration, existed. The attack appeared to be of an anginoid character, though the closest question failed to show any sense of constriction or of pain. The signs, clinically, would demonstrate cardiac degeneration, but I am chary of expression, for I believe that the diagnosis of fatty degeneration of the heart as frequently exists in the brain of the physician as it does in the heart of the patient.

I did not again have an opportunity of seeing her, so can give you no further details of the case. She had been taking strychnia, which I was loth to continue, for when we have a condition of general endarteritis, as in this case, the administration of strychnia frequently precipitates a cerebral hemorrhage.

Another patient, whom I had frequent opportunities of seeing over a period of some weeks, furnished some interesting details of the probable cause of tachycardia. The patient was a woman, forty-four years of age, the mother of eleven children, and had never experienced any sickness except that incidental to child-bearing. She was capable of doing, as she declared it, a good day's work, and had only been interrupted in the pursuit of her duties by attacks of palpitation. These seizures had supervened upon an accident occurring when she was eighteen years of age. The nature of the accident, briefly, was of this character: In crossing a field she had fallen into an unused well, from which she was rescued, with difficulty, some minutes afterward, in an unconscious condition. Physically, she had not been injured, but the shock was of such magnitude as to produce an indelible impression upon her nervous system. The attacks of tachycardia were very infrequent at first, occurring about once in three months, and independently of menstruation, pregnancy, or child-birth. They were also limited as to time, lasting but a few minutes, and accompanied by a slight feeling of prostration which rapidly disappeared. Without any assignable cause, the attacks had lately increased, as to both severity and length. The patient attributed this to the changes consequent upon the climacteric, which may or may not have been the case.

I was fortunate in witnessing two of the attacks, and, while they were not so severe as in the first case mentioned, I believe the condition presented was entirely different in its nature.

The patient's normal pulse was 86, small, but of good arterial expression. There was neither intermittency nor irregularity. The apex beat was in the normal situation, and the systolic power of the left heart entirely efficient. In the first attack her pulse, from being normal, ascended immediately to 230, as nearly as we could estimate. Auscultation revealed a soft bruit at the apex, and immediately confined to that situation, due to the acute dilatation present. The heart beat was coincident with the radial pulse, and no intermittency was discoverable, though a very slight irregularity marked the interference with the ventricular systole, produced by the dilated condition present. The visible and palpable area of impulse was slightly increased in extent, and displaced to the left. There was no dyspnœa, and but a suspicion of cyanosis. She complained of palpitation and weakness, but otherwise was able to answer questions intelligently. The attacks lasted about five minutes, the patient rapidly recovering and the pulse rate resuming its normal character without any subjective symptoms.

Now these two cases represent to my mind two entirely different types of tachycardia, the first being produced, possibly, by myocardial degeneration, the second by profound shock to the nervous system.

As Patton well says, although paroxysmal tachycardia is not associated with any clinically-demonstrable disease of the heart, in the six cases which have come to postmortem there has been shown myocardial disease in three; and if we consider that in these analogous disturbances of cardiac rhythm—tremor cordis and delirium cordi—there is practically always some form of myocardial disease present, we may admit that West's opinion, that the lesion of tachycardia is in the myocardium, is not without some force; still the failure to demonstrate some fault in the nerve supply of the heart does not prove that such does not exist. The great frequency of myocardial disease, and the great infrequency of tachycardia show the latter not to be dependent upon the former alone. Nevertheless, myocardial changes may be a necessary, if not a principal, factor in the production of tachycardia, at least so far as modifying the inherent automatic and coördinate action of the myocardium is concerned.

In a heart muscle which has undergone changes ordinarily not productive of clinical or, possibly, even of pathological evidences of disease, a sudden variation of the usual conditions of circulation, or of innervation, or both, might be productive of such manifestations as tachycardia.

Accuracy in the use of scientific nomenclature is greatly to be desired, and it appears to the writer that when we find the symptom tachycardia—for I am sure it cannot be regarded as a disease entity—associated with definite pathological changes in the myocardium, we should term it essential tachycardia. Where, on the other hand, no clinical or pathological disease-changes are manifested in the structure of the heart, and where its rapid action is apparently due to causes outside the cardiac territory, whether those depend upon changes in the nervous system or passing temporary disturbances in the alimentary tract, the name reflex should be applied to the tachycardia. It cannot be denied that rapid action found with organic disease of the heart is an entirely different phenomenon than that associated with disturbance in some other organ. The effect, ultimately, if sufficiently long continued, will be the same; but in one it is the intracardiac ganglia which is affected by the pathological changes, in the other the nervous stimulation is reflexly conducted.

The restriction of the name tachycardia to those cases in which very violent heart action occurs without obvious reasons has been advocated by Wood, who claims that most of them belong to three classes: (1) those in which there is paralysis of the pneumogastric or inhibitory nerve; (2) those in which the cardiac disturbances are reflex; (3) those in which the affection may be considered as strictly a neurosis. Of the second variety, he observes that he has never seen a case, "though Rommelaere reports one in which he asserts that an extremely rapid action of the heart was due to irritation caused by biliary calculus."

The experience of other authors has furnished confirmatory evidence of the production of paroxysmal and reflex tachycardia from various causes. Thus it is frequently found associated with displacement of one or other of the abdominal organs in both sexes, or serious disturbances of the pelvic organs in the female, with floating kidney, one example of which has occurred to me in private practice; dilatation of the stomach, profuse menorrhagia at the menopause, denoting prolonged irritation of one or more

branches of the abdominal sympathetic as a possible cause. For just as irritation of the solar, renal, or other abdominal plexuses may produce pain or excite muscular action in the organs supplied by the stimulated nerves, so the stimulus may be referred from one periphery to the other, and thus intense impressions produced by disease or misplacement of the abdominal viscera on the sympathetic filaments or ganglia, with which they are endowed, may be transferred to the cardiac branches of the sympathetic or the accelerator center.

To those interested in the literature of the subject I would state that Dill, in the *Lancet*, February 4, 1893, recites a number of cases illustrative of the tachycardia produced by causes outside of the heart—for example, functional disturbances of the alimentary tract.

Certain writers have dwelt upon its origin from nervous causes, though in these cases it may be questioned as to whether we have a real paroxysmal tachycardia, possessing the characteristics which have been mentioned, or simply an exaggerated "heart hurry." In the *British Medical Journal* for February 6, 1897, is published a paper read by Dr. Williams, with two typical cases. He showed spygmographic tracings which brought out the rapid, almost sudden, variation in the pulse rate from 50 to 200 a minute. He claimed that abrupt change from slow to rapid pulse, and persistence of the latter for hours, or even days, characterized the affection. With regard to the gastric origin of this distressing neurosis, if we may so properly call it, Dr. Barnard of Paris gives particulars of an interesting case. The patient was one of our own country-women, aged forty-two years, temporarily sojourning in Paris. She was found flat on her back, not daring to make the slightest movement. The cardiac pulsations were so rapid that their enumeration was impossible. There were no abnormal cardiac sounds, and the other organs were recognized to be healthy. The patient had suffered previously in the same way, prior to her trip abroad, and claimed never to have derived any benefit from any of the remedies administered, including digitalis, the attacks seeming to subside spontaneously. Despite this a belladonna plaster was applied, then an ice-bag over the cardiac region, while bromide of potash was given internally. None of these remedies exercised the slightest control. Then Dr. Bernard, at 11 P.M., gave an emetic of grs. xx ipecacuanha and gr. i of tartar emetic. The vomiting that followed brought the pulse down at once to 112, much to the relief of the patient. On the following morning the pulse was 82, and the lady quickly recovered. Dr. Bernard was led to try an emetic in this case by a remark made by the patient to the effect that, in a previous attack, occurring in London, she dated her recovery from the moment when, "in consequence of the nasty messes prescribed by her doctor," the stomach rebelled and expelled its contents.

In that combination of classical symptoms to which the name of Graves has been attached, the only absolutely constant symptom is tachycardia; but, on the other hand, we have Charcot's authority for the statement that, in some cases of this affection, the tachycardia is paroxysmal and intermittent.

The pathology of tachycardia is still, unfortunately, very obscure. Among other theories it has been attributed to recurrent irritation of the cervical sympathetic, to paresis of the vagus, to a lesion of the myocardium, or of the cardiac nerves or ganglia, and to a central nervous lesion. The great difficulty in constructing a suitable hypothesis lies in the fact that tachycardia may emanate from any one of the sources mentioned, but the limited amount of material would seem to prove that, in the majority of cases, the underlying factor appears to be some structural change in the myocardium. It is probably not in one, but in several, diverse cases that tachycardia originates.

We are too prone to name, and, primarily, regard the greater number of diseases from an anatomical standpoint; the recognizable modification of structure, whether gross or minute, is made the basis upon which our knowledge is established, and even when the disease is studied clinically, it is with more or less expressed reference to the associated or causative structural perversion. So that even when we find myocardial degeneration, we must be careful not to reason too closely to the *post hoc ergo propter hoc*. A broad and comprehensive view of all the circumstances, both recent and remote, must be included in our appreciation of the facts presented in each individual case, otherwise an element of confusion will be introduced fatal to a scientific diagnosis.

The treatment of tachycardia has been unsatisfactory, as is to be expected where so many diverse conditions may give rise to the same symptoms.

Dr. Poulet of Plancher-les-Mines advocates the use of a little known drug found in Alsace, and indigenous to that country, called *coronilla varia*. Domestically, it is given for its cathartic and diuretic properties. He employed a tincture made from the entire plant (one in five). The dose is from ʒss to ʒi. Details are given of two severe cases in which the preparation gave immediate relief.

On general principles, I presume, more than with the hope of accomplishing any definite good, digitalis has been administered. Where there is much dilatation, and yet sufficient potential capability upon the part of the myocardium to respond to the stimulating effects of the drug, something effective might be done between attacks. But digitalis cannot restore disintegrated cellular tissue, and the structural degeneration of the myocardium has generally, in those cases in which tachycardia is found associated with myocarditis, advanced to such a prohibitory extent that we can expect little from the most important drug in cardiac therapeutics.

In the case in which I had an opportunity of administering continuous treatment, and in which digitalis appeared to be of no avail, I gave the fluid extract of convallaria majalis in five-drop doses four times a day, and the patient claimed it had the effect (1) of shortening the attack; (2) of lengthening the intermissions, and (3) of not producing the sense of cardiac constriction which followed the administration of digitalis.

Undoubtedly, for a time, she was much better, but as both of the effects mentioned had occurred previously, when the convallaria was not given, I am inclined to be skeptical of its presumedly beneficial action.

In a third case, which may be described as coming within the lower range of tachycardia, and in which there was marked arterial tension with decided neurasthenic leanings, I gave the bromide and iodide of potassium in combination, the first for its well-known sedative effect, and the iodide for its remarkable efficient action in dilating the peripheral arterioles, reducing the tension, and rendering the work of the heart less arduous.

In conclusion it may be stated that the treatment of tachycardia is the treatment of the condition from which it arises, or with which it is associated. The opposite condition to tachycardia, namely, bradycardia, is frequently met with in applicants for life

insurance, and to those of us who may be interested in that direction the question naturally arises how much significance should we attach to a symptom of that character. I have met with a pulse of 40 in a young man thirty years of age, and the perfect embodiment of health. There was no cause assignable for the slow pulse. It certainly was not a case of fatty heart; there was neither intermittency nor irregularity, and the applicant was not a smoker. He was not aware of the presence of the bradycardia, and his occupation, a jeweler, never brought any stress or strain to bear upon his cardiac functions. And right here I would state that my studies in heart affections, somewhat considerable in the past six years of dispensary and hospital experience, has made me very chary and conservative in expressing an opinion concerning the strength of the individual heart.

We must examine it under various conditions, especially after prolonged exercise, before advancing an opinion as to its power to withstand various emotional or physical demands. The physical examination does not always disclose inherent strength or weakness, and thus it is that frequently we are surprised how successfully a crippled heart—one with an ancient endocarditis, and an apical murmur—will pass through the cyclonic storm of a pneumonia, and respond judiciously to various cardiac remedies, while an apparently healthy heart appears to be irresponsive to all treatment. One of our colleagues died a few weeks ago from pneumonia. The pulse rapidly ascended to 150 on the second day of the disease. His heart was apparently normal in every respect.

I have seen bradycardia in a man of sixty-five years, the pulse descending to 20, but perfectly accounted for by reason of the cardiac degeneration present, associated with a scleroses of the coronary arteries.

Thus, every heart is a law unto itself, and the propounding of snap diagnoses in the realm of cardiac diseases is to be strongly condemned. I mention bradycardia simply for the purpose of provoking discussion.

HEMORRHAGIC APPENDICITIS AS THE FIRST MANIFESTATION OF PURPURA HÆMORRHAGICA.*

By NATHAN JACOBSON, M.D.,
SYRACUSE, N. Y.

PROFESSOR OF CLINICAL SURGERY, SYRACUSE UNIVERSITY, COLLEGE OF MEDICINE; SURGEON TO ST. JOSEPH'S HOSPITAL.

I DESIRE to call attention to a condition which seems to me quite unique. At least I have been unable to find a record of its counterpart.

I was asked to see E. T. on February 23, 1901, by Dr. Curtin of this city. She was thirty-seven years of age and unmarried. The patient resided in Buffalo, and had been visiting in Syracuse for three days. Before leaving home she had suffered from severe pains in the right side of the abdomen, associated with some general abdominal disturbance. Dr. Curtin had been called to see her on the 21st inst. On the following day—that is, the day before my visit to her—there was apparent improvement. When I saw her the right-sided abdominal pain was very acute. Tenderness was marked over the site of the appendix. She complained also of pain in the region of the gall-bladder, and located a third painful point to the right of the umbilicus. She was rather stout, and to this condition I ascribed the fact that the rigidity of the muscles was not as evident as one usually finds it in appendicitis. However, there was considerable resistance in the right half of the abdomen. There was a good deal of abdominal distension, which was much relieved by an evacuation of the bowels, following the administration of an enema. Temperature was 104.5°; pulse, 132. There was some hesitancy as to the diagnosis, because of the various points of tenderness, and yet it was most intense at the site of the appendix. Both Dr. Curtin and myself considered it to be an attack of appendicitis.

I operated upon her at St. Joseph's Hospital. The bleeding was very profuse. A large number of vessels required ligation. The subcutaneous fatty layer was about two and one-half inches thick. The omentum was also very fatty. The appendix was five inches long. It was apparently acutely inflamed. At least it presented a very red appearance. Later, upon section, it was found to present numerous areas of hemorrhage into its substance. There was no free bleeding into the cavity of the appendix. This was distended by a mucoid discharge. The hemorrhage was entirely interstitial. The wound was closed without drainage. The patient bore the operation well. She was extremely hypersensitive, and for a day or two required the occasional administration of codeine hypodermically to relieve her. Two days after operation she was seized with intense pain in the left side of the chest. With its appearance the temperature, which had fallen to nearly normal after the operation, ran to 102°. The following day the pain, though persistent, was not so severe. Four days after operation she developed a hacking cough, and, during the evening, raised a large quantity of bright red blood. During the same night she had a profuse nasal hemorrhage. On the following day a number of petechiæ appeared on the left leg above the site of the head of the fibula, while on the calves of both legs numerous ecchymoses were found. On the abdomen there were also petechial points, and at the sites where hypodermic injections had been given free bleeding had occurred subcutaneously. There were no further skin manifestations. The heart at no time presented any evidence of disease, nor were the joints ever implicated. There never was any hemorrhage from the bowels, nor from the kidneys. She never vomited, consequently there was no evidence of gastric hemorrhage. She had a number of attacks of epistaxis, and the bronchial hemorrhage was very persistent. There were but few days from the 3d to the 20th of March during which she did not expectorate more or less blood and blood-stained mucus, and on some of the days the bleeding was very profuse. During this time the temperature was rarely high. Up to the 10th of March it did not go above 100°, but on this date it rose to 102°. The elevation was to be accounted for by the appearance of a stitch abscess. This gave us no serious trouble, but required attention for some time. Aside from this, there were no surgical complications. There was, however, during the week of March 13 to March 20, an evening rise of temperature which never exceeded 102°, and a morning remission to 99° or 100°. During this period there was a persistent cough. On the 20th of March Dr. Curtin suggested the administration of suprarenal extract. Coincidently with its administration there was cessation of the hemorrhagic manifestations, and a subsidence of the fever. The patient gradually improved from this date on, but remained in the hospital until April 13, at which date she was discharged, cured. Since then she has remained in perfect health, and has never had any recurrence of hemorrhage. There was no history

*Read at a meeting of the Medical Society of Central New York.

of a hemorrhagic diathesis, nor is there any such family tendency.

The case seems to be clearly one of purpura hæmorrhagica, in which the first evidence was hemorrhage into the appendix. It is interesting to note that there appeared, in consequence of this bleeding, manifestations so closely resembling those ordinarily encountered in appendicitis, that it was impossible to make a differential diagnosis. Had no subsequent hemorrhage appeared, the case might have been put down as one of appendicitis, and would not have been regarded simply as one of the manifestations of an attack of purpura hæmorrhagica. The condition differed entirely from anything I had ever seen. The hemorrhagic areas were the result of minute hemorrhages into the substance of the appendix. There was no free bleeding into its lumen.

In the issue for December 21, 1874, of the *Berliner klinische Wochenschrift*, Professor Henoch published an address delivered a short time previously at a meeting of the Berlin Medical Society, in which he called attention to a form of purpura hæmorrhagica with marked gastrointestinal symptoms. His four patients were aged respectively four, eleven, twelve, and fifteen years. Two were boys and two were girls. In three of the cases the characteristic joint disturbances, with purpuric spots upon various parts of the body, appeared in advance of any gastric or intestinal symptoms. The fourth case was one of dysentery, associated with purpuric areas upon the elbows and thighs. Each of his four patients discharged blood with the stools, but none of them had the slightest hemorrhage from any other mucous surface. Another singular feature common to all was the disposition to recurrence of the symptoms, with periods of remission, so that one patient had five attacks in the course of seven weeks; another four in as many weeks; a third had five attacks, and in the fourth a similar history is mentioned.

While in each there was more or less abdominal tenderness, in not a single instance is it mentioned that this was located in the region of the appendix. The disturbance in all of them seemed to be general instead of local.

He refers to three other cases of which he had found record. The first was reported by Vallin, and was that of a soldier who, while sick with articular rheumatism and purpura, had bloody evacuations of the bowels. The second was a patient under the care of Wagner, who, in addition to his purpura, had albuminuria; he died of peritonitis. At the autopsy numerous superficial ulcerations of the intestinal mucous membrane, covered with croupous and diphtheritic exudate, were found. The third case was recorded by Ziemssen, in which intestinal symptoms present in a case of purpura were found post mortem to be due to ulcerations of the ileum at no less than 150 different points. Death was due to fibropurulent peritonitis.

Other and more recent writers report similar experiences. It is certainly evident that our patient's case cannot be classed with these. Her manifestations differed altogether from theirs. In her case there were no preceding joint or skin lesions; nor were the intestinal symptoms at all alike. Her very first symptoms indicated that the appendix was the primary site of trouble. No other part of the intestinal tract was at any time affected. Coincident with the appearance of the purpuric spots upon the legs was the occurrence of bronchial and nasal hemorrhage. The persistent hemorrhage was altogether from the respiratory tract. There was also no disposition to frequent recurrence of symptoms, as is seen to be so constant a manifestation in Henoch's purpura.

Despite a very extensive search in medical literature, I have been unable to find a case which is a duplicate of the one reported. Those referred to form the only group of cases I have found presenting intestinal lesions in purpura hæmorrhagica.

To me the point of greatest interest is the fact that hemorrhage into the appendix, occurring as the first manifestation of a purpura, should produce symptoms so strikingly like an inflammatory process as to warrant the designation of hemorrhagic appendicitis.

SUBCUTANEOUS ABSCESSES DUE TO THE GONOCOCCUS, IN A CHILD TWO YEARS OF AGE.

By MILTON A. GERSHEL, M.D.,
NEW YORK.
HOUSE PHYSICIAN MOUNT SINAI HOSPITAL.

The case which I wish to describe presents two features of very marked interest; first, the occurrence of subcutaneous abscesses complicating gonorrhœal infection, and second, the presence of such a complication in a young child.

The history, in brief, is as follows: The child, a male, two years of age, was admitted into the children's ward of the Mount Sinai Hospital, in the service of Dr. Koplik, November 15, 1901, suffering from an attack of typhoid fever. (The Widal reaction was positive in the dilution of 1 to 50.) A few days after admission the child developed an acute anterior urethritis, which was proven to be gonorrhœal in nature, by the same methods as were used in the study of the abscesses about to be described. The source of infection could not be established. A week later I found a subcutaneous indurated area, about two centimeters in diameter, situated to the left of the anus. The skin over the area was of a pale red color; firm pressure applied to this area did not diminish the size of the mass.

The mass was aspirated, and some brownish-yellow pus obtained. The swelling increased in size, and two days later was opened and about 2 c.c. of pus were evacuated. The cavity was irrigated and probed, but no communication with the rectum or prostate was found. There was no discharge from the rectum; the prostate was normal in size.

Three days later a smaller area of induration was found to the right of the anus; at first it was about the size of a pea, but it gradually increased in size, and when it was incised was found to contain 4 c.c. of pus similar in character to that obtained from the other abscess. Exploration of this cavity also failed to demonstrate any connection with any deeper structures.

The walls of both of the abscess cavities were covered by small, dark red, easily-bleeding granulations. The healing process was very slow, four weeks elapsing before the wounds were entirely healed. At no time was there any inflammation of the prostate gland or of Cowper's gland, nor were any remote complications of the urethritis found.

Bacteriological Examination.—The cover-slip preparations made from the pus of both abscesses showed the presence of numerous diplococci, mainly intracellular, decolorized by the Gram procedure, and resembling the gonococcus in morphology. No other bacteria were present in the spreads. Streak inoculations of the pus were made on plates of serum-glucose-agar (prepared after the method recommended by Dr. E. Libman).* At the end of twenty-four hours there was no growth, but at the

**Journal of Medical Research*, 1901.

end of forty-eight hours there was a very marked growth characteristic of the gonococcus. Secondary transplantations on bouillon and agar remained sterile. Inoculations on serum-agar gave a similar growth of gonococcus to that on the serum-glucose-agar, but the growth was less profuse.

It is evident that we have to deal here with a case of subcutaneous abscesses following gonorrhœal urethral infection. A remarkable feature of the case is that, notwithstanding the close proximity of the abscesses to the rectum, there was no secondary invasion by intestinal bacteria, such as one would reasonably expect.

Cases of abscesses due to the gonococcus are very infrequent in literature; I have been able to find altogether eleven cases, besides the one here reported. Nearly all the cases have been collected by Young in his paper on gonorrhœal infections in the Welch "Festschrift," and in what is to follow we shall quote largely from this paper:

Experiments made in 1891 and 1892 by Wertheim and Steinschneider, in the hope of causing subcutaneous abscesses in the human being by inoculation of pure cultures of the gonococcus, resulted in slight or no lesions at all, and it was therefore believed that the gonococcus could not cause subcutaneous abscesses. Later clinical experience, however, proved that the gonococcus could cause such infections.

The first case was described in 1893 by Lang and Paltauf. The abscess was situated on the dorsum of the hand, and probably arose in connection with a tenosynovitis. Horwitz later reported an exactly similar case.

In 1895 Bujivid described a case in which there developed in the course of a chronic posterior urethritis four intramuscular abscesses, situated in front of the left elbow, in the right popliteal fossa, on the inner side of the left leg and over the right external malleolus.

In 1897 Jundell reported a case of extensive subcutaneous abscess formation due to a gonorrhœal tendovaginitis of the tibialis posticus muscle.

In all the preceding cases the gonococcus was found in spreads and in cultures on serum media.

Young observed five cases. The first was one of periurethral abscess, located on the inferior surface of the penis, just behind the frænum. It could not be evacuated into the urethra by pressure. An external sinus or a communication with the urethra could not be found. The gonococcus was demonstrated in spreads and cultures.

The second case was one of large perineal abscess. The patient presented an elongated swelling in the perineum, measuring 8 by 4 cm. in area, and bounded by the attachments of the deep layer of superficial perineal fascia, viz., triangular ligament and ischiopubic rami. The abscess was situated external to the bulbocavernosus muscle and underneath Colles' fascia. In this case, too, the presence of the gonococcus was demonstrated in cultures. Young draws attention to the occurrence in the wall of the abscess in this case of dark red, readily bleeding granulations. He states that he has observed similar appearances in the synovial membranes of gonorrhœal joints, and considers them characteristic of gonococcus infection.

Young's third case was one of multiple gonorrhœal arthritis, in which the gonococcus was obtained in pure cultures from the knee-joints. The knee-joints were opened, irrigated, and then closed. Fourteen and seventeen days later superficial subcutaneous abscesses were found in the regions of the incisions without any demonstrable communication with the joint cavities. Intracellular diplococci decolorizing by Gram were found in the spreads; cultures taken on ordinary media remained sterile.

In the fourth case he observed subcutaneous abscess-formation of the dorsum of the hand, following closed incision for a gonorrhœal arthritis of the wrist. Gonococci were demonstrated culturally in the fluid obtained from the joint, but in the pus later found in the subcutaneous abscess, gonococci were demonstrated by smears only. (This case can nevertheless be considered as an undoubted instance of gonorrhœal abscess, because of the positive cultural findings in the fluid from the joint, and the lack of growth in ordinary media, after inoculation with the pus from the abscess).

The fifth case was one of abscesses and fistulæ of the perineum and scrotum, of three-years' duration, following gonorrhœal stricture. The gonococcus was demonstrated in smears, together with some bacilli similar to the colon bacillus. Cultures were not made on media suitable for the growth of the gonococcus. On agar the colon bacillus alone was found. This case we are not quite willing to accept as an undoubted instance of gonorrhœal infection.

Besides these cases collected by Young, we have been able to find two further cases. The first case, described by Scholtz, is that of a robust man, eighteen years of age, in whom there developed, during the course of an otherwise uncomplicated attack of acute gonorrhœa, a small, flat, tender nodule directly under the skin, near the root of the penis; from it to the glans, near the coronary sulcus, a thin cord was found (apparently an inflamed lymphatic). Within eight days the mass had become much larger and fluctuated. It opened spontaneously after the use of mercurial plaster, and a little less than 1 c.c. of bloody pus was obtained, from which the gonococcus was obtained in pure culture. The abscess lay directly under the skin in the subcutaneous tissue, and had no connection with the corpus cavernosum. This case gives us a very convincing demonstration of abscess formation due to the extention of the gonorrhœal infection through the lymphatics.

The second case is described by Dreyer. In his patient there developed a swelling on the dorsum of the penis, accompanied by chill, nausea, vomiting, headache, and slight temperature. About 2 cm. from the coronary sulcus, under the foreskin, a nodule the size of a hazelnut was found. The skin over it was red, and a lymphatic could be seen leading from it. Later it was opened and chocolate-colored pus evacuated. The urine was always negative, but the patient had suffered from a gonorrhœa one year previously. Dreyer says that he found typical intracellular diplococci in spreads, but made no cultures. (This case probably cannot be definitely claimed to be a gonococcus infection.) He refers to some work by Nobl, who made histological studies of the lymph cords in cases of gonorrhœa. In the study of nine cases he was able to demonstrate gonococci microscopically five times. He did not succeed in obtaining the organism culturally, but other bacteria, more particularly pyogenic bacteria, also were not found and could not be cultivated. Nobl attaches great significance to these findings, as regards the demonstration of the method of general infection by means of the lymphatics.

On looking over all the cases which we have mentioned in the course of this paper, it will be seen that in only two of them (if we exclude Dreyer's case) was there a condition analogous to the one found in our case. These are the case of periurethral abscess described by Young and the case of abscess of the dorsum of the penis described by

Scholtz. Only in these two cases and in our case was an abscess found directly under the skin, having no communication with the deeper parts, and not being dependent upon inflammatory changes in the joints, muscles, or tendon sheaths. Our case, like the case of Young and that of Scholtz, must be looked upon as an infection by way of the lymphatics.

I wish to thank Dr. Koplik for placing this case at my disposal, and Dr. Libman for his kind assistance.

IMBALANCE AND INSUFFICIENCY OF THE EYE MUSCLES.*

By R. C. MATHENY, M.D.,
GALESBURG, ILL.

The subject of imbalance and insufficiency of the eye muscles is interesting because of its comparative newness in the science of medicine, its systematic study extending back only a few years. It is especially gratifying because it does not open up perplexing questions which cannot be answered, but, on the contrary, offers most brilliant results to the painstaking student. As an etiological factor in the cause of disease it has already assumed great importance. And while, perhaps, hyper-enthusiasts have been over-zealous in their claims, it is surely true that physicians, as a rule, have sadly underrated it.

If the chief object of the physician be the alleviation of suffering and the cure of disease, any one true to such convictions will seek aid wherever he can find it. And as the subject of medicine grows more and more intricate with increasing knowledge, the physician, the surgeon, and the specialist will become more and more dependent on each other.

Prior to 1880 probably no one ever operated on the ocular muscles for any condition other than strabismus. Orthophoria and heterophoria had no place in medical nomenclature. The countless sufferers sought relief in vain, and physicians fought a concealed and unknown foe, and consequently failed.

The world owes much to Dr. Stevens of New York for his studies of the ocular muscles, and the scientific data he has given the profession. The brilliant results that have been achieved by him and others along this line have not only brought glory and fame to them, but what is vastly more important, have brought surcease of suffering, and with it the capacity to thousands to enjoy life.

The terminology for indicating the relationship, normal and abnormal, between the ocular muscles now generally used, was that offered by Stevens and adopted by the ophthalmological section of the American Medical Association in 1891.

Orthophoria is the term signifying perfect balance of the ocular muscles, when the head is held erect and facing directly forward, and the eyes looking straight ahead. The condition indicates that all of the external muscles of the eyes are perfectly developed with the proper origins and insertions. And also that the various innervations are normal. Thus all the various and complicated movements of the eyes are performed without strain or friction. The visual axes are thus easily kept in the same plane, the convergence of the eyes is always perfect, and the various vertical, horizontal and oblique movements are performed in perfect harmony.

Orthophoria, however, may exist; that is, there may be a perfect balancing of the muscles, and still the musculature not be normal. For instance, all of the muscles of the eyes may be relatively weak. The ducting or verting power is not as great as it should be. And very serious mistakes have been made in this regard. The eyes were considered normal because orthophoria was present and an inherent weakness in all of the muscles was overlooked, because the balance was perfect. And where there is a perfect balance, but a general weakness of the muscles, the condition is called asthenic orthophoria. Many a case has gone unrelieved, and the eyes dismissed as a causative factor in suffering because the balance of the muscles was perfect and no error of refraction existed; whereas all the time the eyes were the offending members because of the asthenic condition of the muscles. The eyes can never be pronounced innocent in any case until the ducting and verting power of each separate muscle has been determined.

Any condition which departs from orthophoria is termed heterophoria, and this may be one of very many conditions.

Esophoria is the term applied to that condition in which there is a tendency of the visual axes to converge. It may be due to an excessive development of one internal rectus or both of the interni. It may be due to an under-development or weakness of one externus or both externi; or the interni may be attached too far back, and yet the inherent strength of the muscles be normal. These are the chief causes of esophoria, but there are others which will not be mentioned.

Exophoria is the opposite from esophoria, and in this condition there is a tendency for the visual axes to diverge. And in exophoria the causes are the reverse of what they are in esophoria. Briefly, the externi are too strong, or the interni are too weak, or the attachments of the muscles may be to blame.

Hyperphoria is that condition in which the visual axis of one or both eyes is too high. Catophoria is that condition in which the visual axis of one or both eyes tends too low.

With the study of these four general divisions of muscle imbalance and the methods introduced for their relief, came some very gratifying results. Some bad work was done, as is always done when some novel and brilliant discovery in medicine or surgery is made known. Surgeons indiscriminately cut eye muscles without scientific data and due consideration of all possible errors, consequently much mischief was done.

It is strange that with the knowledge of the possibilities offered in correcting heterophoria of the recti muscles the obliques were completely overlooked, and yet their function was fully understood. It was not until 1895 that Stevens began the study of the obliques. A short time before this Von Graefe had made an indefinite reference to the subject, but gave no data to the profession, and the probabilities are that he had given the subject but little if any attention.

It is now known that an imbalance or insufficiency

*Read before the Military Tract Medical Association, Monmouth, Ill., October 16, 1902.

of the obliques may produce very serious symptoms, and its correction is followed by the same happy results that follow the correction of the other muscular errors.

Cyclophoria is the term applied to an imbalance of the oblique muscles, and the words plus or minus are added to designate an insufficiency of the superior and inferior obliques respectively.

The word insufficiency, which was formerly applied to muscular errors, was incorrect in some instances. The word would indicate a weakness or undeveloped condition of the muscle, which in many instances did not exist. For instance, an internus might be fully developed and quite normal, and yet the antagonizing externus, being excessively developed, or perhaps improperly attached, would cause undue strain on the internus. The fault in such a case is with the externus, and remedial treatment should be directed to it rather than to the inoffending internus.

Imbalance is the word offered by Dr. George M. Gould of Philadelphia, and it has been generally adopted. It is properly applied to all cases of heterophoria, whether there is a true insufficiency of one or more muscles, or an excessive strength or development of one or more muscles, and also when there are improper attachments of the muscles.

The symptoms of heterophoria are numerous and varied. Very often they are referred to the eyes themselves, but more frequently to other organs or parts of the body—the various kinds of headaches playing the chief rôle.

Persons with weak physical or nervous systems are the greatest sufferers from heterophoria, and the neurasthenic is an intense sufferer from this cause. Frequently persons who have been previously well, and free from all pain or indisposition on convalescing from some debilitating illness will begin to show serious symptoms that result from muscle errors. It often first manifests itself after a pregnancy and confinement. Frequently the indisposition in these cases is naturally attributed to the general effects of the puerperium, and such persons find relief only when the ocular error is corrected.

Headache, as mentioned before, is probably the most common of all symptoms of heterophoria. It may be referred to the brow, top of the head, or neck. It is frequently periodic in character, and usually comes on after excessive use of the eyes. The headache which one has on awakening in the morning is seldom if ever due to eye disturbance. Sleep generally relieves the headache from eye strain, whether of heterophoria or refractive errors.

It might be well here to recall the difference between heterophoria and errors of refraction. They are quite distinct, and one may be present without the other, or both may be present.

Vertigo and nausea are frequently caused by heterophoria, and in such cases there is generally insufficiency of the oblique muscles. You have probably all known of cases of paresis of the eye muscles involving the obliques in which the eye is torted. Nausea and vomiting are the earliest and most marked symptoms in such cases. And these symptoms are occasionally caused when there is insufficiency of the obliques.

Epilepsy, in all probability, is sometimes caused by heterophoria. I now have a case under observation in which, all other methods having failed in the hands of the physician who has the case in charge, the patient was referred to me, and there was found 9° of exophoria. Two-thirds of this amount was relieved by prisms, with the result that the epilepsy has almost entirely disappeared. Very many cases of undoubted epilepsy have been permanently cured by operations which brought about a perfect balance of the eye muscles. Every case of epilepsy should be rigidly tested for heterophoria, and if it exists it should be remedied. Of course this presupposes that the exact nature of the heterophoria is diagnosed and the proper operation performed for its relief.

Ranney, in his work on "Nervous Diseases," page 481, says: "One of the most remarkable cases that ever came under my observation was that of a combination of chorea, epilepsy, and idiocy, in a girl about eleven years of age, who completely recovered her health, strength, and mental faculties when a refractive error in her eyes was corrected by glasses, and a serious combination of muscular defects in the orbit was adjusted by tenotomy. This case was one that I saw three years ago in connection with the practice of Dr. Stevens. At the first examination the child could not walk without being supported on both sides, drooled constantly, talked unintelligibly, answered questions with apparently little conception of their import, could hardly sit unsupported in a chair on account of chorea, had epileptic seizures repeatedly during the day and night, and presented a pitiable and apparently hopeless aspect. I saw her about a year after the operations were performed, at the request of Dr. Stevens. I found her free from chorea and epilepsy, able to run and skip a rope unaided, rosy-cheeked, and in full possession of her mental faculties."

Doctors Dercum and Parker of the University of Pennsylvania have reported the results of their studies and experiments in relation to the eye muscles, showing that very severe functional neuroses may be caused by heterophoria and eye strain.

Neurasthenia is undoubtedly greatly affected by heterophoria and errors of refraction, and these important factors should never be overlooked. In numerous cases of neurasthenia such brilliant results have been obtained by simply correcting errors of refraction and relieving undue tension of imbalanced muscles that it can be advisedly said that every neurasthenic should have his refraction and eye muscles carefully examined.

Asthenopia is naturally an almost constant symptom of heterophoria. The distress and fatigue that accompanies these cases is often supposed to be due to some refractive error which does not exist, and such persons try glasses in vain. Only when treatment is directed to the muscles is relief found.

Likewise diseased conditions of the lids and conjunctiva are often seen as a result of heterophoria, and the customary remedial agents fail in these cases, but the symptoms rapidly disappear when the imbalance is corrected.

The treatment of heterophoria is based on mechanical principles, and demands a knowledge of the function of the eye muscles, the anatomy of the eye and its appendages, and an exact understanding of physics as applied to binocular vision, based on the law of corresponding retinal points. In order to perform its function in perfect harmony with the other, each eye is supplied with six extrinsic muscles. Any one of these muscles, or a combination of two or more of them, may be the cause of the imbalance. Therefore, it is necessary to study each muscle separately, and also in its relation to the other muscles; its relative as well as its inherent strength. The verting as well as the ducting power of each muscle should be known.

When the cause of the heterophoria is known the treatment should be directed to its relief, and a perfect readjustment of the muscles brought about. One or more muscles may be at fault.

In esophoria, for instance, the tendency to convergence may be due to an error in one muscle of one eye. It would be a gross mistake, therefore, to operate on one of the muscles of the other eye, as is frequently done, although that temporarily balances the visual axes.

Likewise, also, if the internal rectus is too highly developed, while the external rectus is of normal strength, it is unjustifiable to operate on the normal muscle—but always on the one which is abnormal.

The above suggestions are made simply to call attention to the importance of directing the line of treatment to the proper muscle or muscles, and not to do a tenotomy or advance the attachment of a muscle simply because such an operation would tend temporarily to balance the external muscles.

Non-surgical treatment can accomplish much in low degrees of heterophoria. Prisms which partly alleviate the tension by favoring the weaker muscle are often worn with comfort and afford relief. But, of course, the wearing of prisms does not cure the heterophoria. They simply permit the eyes to converge or diverge, and still maintain binocular single vision.

As was said before, there sometimes exists cases of asthenic orthophoria—that is, the muscles are properly balanced, but they are intrinsically weak. This condition often causes much suffering, and the question arises what can be done for such cases. Undoubtedly much can be done to develop these weak muscles, but the treatment is slow and requires great patience and perseverance. But when the blood supply is not wholly inadequate, and the faulty innervation is not irremediable, the eye muscles can be developed the same as any other muscle. Systematic exercise, properly carried out, has been proven to be of benefit. There are several methods of doing this, which I will briefly mention:

In cases of exophoria, when it is desired to strengthen the interni, a small object is placed at arm's length from the eyes, and fixed with both eyes. It is now gradually brought to within about eight inches of the eyes, and then removed to the farther point again. This exercise, carried out systematically and regularly for two or three minutes each day, and increasing the time to five or six minutes, will frequently be of benefit. The exercise should always stop short of fatigue.

As a general exercise for all of the recti muscles, it has been recommended that the patient stand with his back to the center of a wall of a room fifteen feet square, with his head in the primary position. A small object is placed at either end of the opposite wall on a level with the eyes, and one also at the lower and another at the upper margin of the wall. Then the patient regularly rotates the eyes from one lateral object to the other for a short time, and from the upper to the lower object. This exercise carried out systematically and regularly is often helpful.

Exercise with prisms is probably the best general method. The principle involved in exercise by the use of prisms is that of compelling the weaker muscles to do more work than is naturally required to fix a given object with both eyes.

There are two general methods of carrying out the principle. The one which has been chiefly advocated by Dr. George M. Gould of Philadelphia is to place before the eyes prisms with their bases toward the stronger muscles, and directing the patient to fix a small distinct object, preferably a small gas light or candle, at varying distances.

Placing the prisms thus compels the weaker muscles to overcome the effect of the prisms in order to maintain single binocular vision. The patient is required to wear the prisms for a few minutes at a time, and the exercise is to be repeated several times a day. Gradually the strength of the prisms is increased until the limit of the ducting power of the muscles is reached.

The other method of exercise by prisms is that advocated by Dr. G. C. Savage of Nashville, Tenn.: Weak prisms, 2° or 3° being set in a frame are placed before the eyes, and the patient fixes the object at, say, twenty feet. The prisms are held thus before the eyes while he counts one, two, three, at intervals of about a second. The prisms are then raised, the patient still fixing the object, and the same count repeated. The prisms are then again placed before the eyes for the same length of time, the exercise is continued for a minute or two the first day, and the time is gradually increased to five minutes. The exercise is performed only once or, at most, twice a day. Strong prisms are never used in this method.

As said before, either method to be of benefit must be carried out systematically, regularly, and persistently.

THE MATERNAL IMPRESSION SUPERSTITION.

By EDWIN TAYLOR SHELLY, M.D.,
ATCHISON, KANS.

THE following excerpts from the pages of standard modern textbooks furnish, it is hoped, a sufficient excuse for discussing seriously at this late day, in a medical journal, the subject of maternal impressions.

The "American Textbook of Obstetrics" refers to the subject as follows: "Structural alterations in the growing fœtus may be effected, modified, or perverted by psychical influences. Certain fetal disorders may result from maternal impressions. Monstrosities do at times so occur. Physiologists admit, and observations prove, that the maternal emotions do affect the development of the exterior of the fœtus. Likewise may the mental development be altered in its complex and delicate organization. Idiocy may so result."

Hirst's "Textbook of Obstetrics" contains the following observations on the subject: "Maternal impressions may affect the embryo or fœtus. There occur well-authenticated cases of congenital defects or peculiarities, which bear too startling a resemblance to the cause of the impression to be dismissed as mere coincidences. One of my patients, less than six weeks pregnant, was, on one occasion, seized by the ear and dragged about the room by her enraged husband. The child born at term had a triangular piece lacking from the lobe of the corresponding ear. Profound impressions upon the mother certainly influence the physical development of her offspring. The idiocy of Barnaby Rudge, due to maternal shock and fright, is a fiction founded upon fact. The horror of King James at the sight of a naked sword may well have had its origin in the murder of Rizzio before the eyes of the pregnant Queen Mary."

Dorland's "Modern Obstetrics" winks at the subject in the following manner: "Unpleasant and painful scenes or impressions should be avoided, so that the possibility of some so-called maternal impressions may be prevented."

In addition to the above authoritative utterances

on the subject, it may not be out of place to cite the following declarations contained in a pamphlet called "Hygiene in Maternity," issued by a well-known eastern firm engaged in the manufacture of surgical dressings: "Thousands of children are, by unpleasant impressions on the mother's mind, rendered victims of untruthfulness, disobedience, together with malicious, threatening, and even murderous natures. The child is most liable to be affected physically during the earlier months; mentally during the latter months of pregnancy. At any time unpleasant mental impressions may produce 'marks.'" In answer to an inquiry, the publishers of the pamphlet wrote as follows concerning the above quotation: "This statement was made on quite eminent authority. It was originally made by a woman physician, and afterward passed through the hands of several eminent authorities, some of whom allowed it to pass unchanged, and others modified it in certain respects, until it appeared in the present form."

It really seems incredible that our modern textbooks of obstetrics should contain such antediluvian notions on the subject of maternal impressions as are embodied in the above quotations; and it ought not to be a very difficult task to show that such utterances would far more fittingly embellish the garrulity of a Sairey Gamp than adorn the teaching of twentieth-century obstetricians. The only thing that lends plausibility to the maternal impression theory is the fact that, very rarely, the occurrence of violent emotion or mental shock in a pregnant woman is followed by the appearance of so-called "marks" in her child at birth. The very few coincidences of this sort should, however, weigh no more heavily in favor of this theory than should the much more frequent instances count against it when such markings cannot be accounted for by any impressions which the mother can recall. In addition to these unexplained markings, there remain to be noted the innumerable occasions upon which expected "marks" fail to appear at birth, notwithstanding the occurrence of the most profound impressions or shocks during pregnancy.

Birth-marks are structural aberrations which, in the very nature of things, must originate in cellular accidents very early in fetal development —very much earlier, in fact, than the mental impressions to whose occurrence these deformities are attributed usually take place. It is a well-known fact that animals and plants frequently exhibit so-called "marks," analogous to those found in man, and yet it is doubtful if anyone—even a professor of obstetrics—would try to explain their occurrence by the maternal-impression theory.

There is no reason to believe that nature gives the female parent any greater power in determining the character and constitution of the product of conception than is granted the male parent. This rule holds true in the vegetable kingdom and in the animal kingdom, aside from man, and there is no good reason to believe that it does not hold equally true in his case. If the correctness of the maternal impression theory be, however, conceded, the logical conclusion must be that nature is biased, and that the influence of the father on the organization of his offspring is entirely subservient to the nervous irritability and mental impressionability of the mother during pregnancy. If this were true it would be unfair to both parents, as well as to their child. As nature is never unjust, the theory is presumably untrue.

The principal grounds upon which this theory can be proven untenable are, however, anatomical and physiological. Immediately upon the maturation of a human ovum and its expulsion from the Graafian follicle, the solution of continuity between the woman and her ovum is complete. Even though impregnation of the ovum occur, and its anchorage to the wall of the womb for future growth and development take place, his assertion still remains true, for at no time during intrauterine life is the connection between the fœtus and the womb other than one of contiguity—never one of continuity. Even in the placenta this fact appears very conspicuous in the arrangement whereby the blood of the mother and the blood of the child do not mingle directly, but only by osmosis.

The relation between the nervous system of the mother and the nervous system of the fœtus is not even one of contiguity, for the gap between them extends throughout the entire length of the umbilical cord and the thickness of the placenta, as no nerves have ever been discovered in either one of these organs. In fact, it would be impossible for the child to be more completely separated from the mother and still be nourished and retained within her body.

The setting hen patiently hatching her chicks is physiologically little, if any, more separated from her embryo chicks than is the mother from her embryo child. The mother supplies her embryo with nourishment, heat, and an abiding place. The hen does no less. In the latter instance, however, the abiding place, the nest—is made to order; in the former, the abiding place—the womb—is ready-made.

Why birth-marks occur and monsters develop no one knows. But, in any event, to explain their appearance by claiming that it is possible for a nervous or mental influence to leap across the chasm which separates the nervous system of the mother from the nervous system of the fœtus and then register an effect so mighty and so selective as to produce the various structural and physical abnormalities known to teratology, is utterly preposterous.

If a maternal impression can be so miraculously powerful as to produce a serious structural catastrophy in a fœtus, why is it not powerful enough to cause, at least occasionally, a similar lesion in the pregnant woman herself? The path from her brain to her own tissues is certainly a less tortuous route than the one from her brain to the tissues of the fœtus.

The appearance of a nævus on the face of a child is usually ascribed to the mother's having seen a burning building at some time during her pregnancy and having thoughtlessly placed her hand over her face to protect it from the heat and glare of the fire. If this etiological explanation be correct, why is it that such psychic dynamics is unequal to the feat of producing, never so rarely, a nævus on the face of the mother?

If viewing the death struggle of a toad may cause a maternal impression sufficiently powerful to change a properly developed fœtus into a horrible monster; and if the slaying of this toad may cause blood to appear in the milk of the slayer's cows—a retributive phenomenon quite common in the days of our grandmothers—why is it that witnessing such a spectacle is never potent enough suddenly to transform the impressionable prospective mother into a hideous exencephalus?

The general prevalence among medical men of the belief in the maternal impression delusion is, of course, a great stigma upon our profession; but this is not all. Because of the fact that physicians fail to combat, as they should, this medical anach-

ronism, the lay mind has remained saturated with it. Consequently nearly every expectant mother is continually in greater or less dread of "marking" her unborn child by something unpleasant she may inadvertently see or feel or hear; and in case an imperfect child be born, the mother is led to believe (excepting in a case like that reported above by Professor Hirst) that she is probably chiefly to blame for the appearance of the deformity. Surely the grief of the innocent mother of a congenitally deformed child is great enough without our adding to her distress by trying to throw upon her the responsibility for the unfortunate condition of her baby.

All obstetric authorities unite in urging the necessity for complete mental serenity in the pregnant woman; and yet nearly all of them do their utmost to disturb that serenity by keeping alive this medieval superstition of maternal impressions. What right-minded physician can fail to feel the keenest distress as he contemplates the numberless and slumberless hours of anxiety spent by hosts of thoughtful and sensitive mothers because of their belief in this unscientific, absurd, cruel notion.

Let us brush this dusty old cobweb from the increasingly radiant chamber of scientific medicine, and thereby relieve the sacred period of motherhood of a horrible spectre.

PARAFFIN INJECTION IN A CASE OF SO-CALLED SADDLE-NOSE.

By FRANCIS ALTER, M.D.,

TOLEDO, OHIO.

LATE RESIDENT-SURGEON OF THE NEW AMSTERDAM EYE AND EAR HOSPITAL, NEW YORK CITY.

THE man whose case I report has been afflicted with the deformity called saddle-nose for the past fifteen years. He gives a history of luetic infection at the

age of twenty-two, he being now fifty-five years old. The course of the disease was turbulent with many relapses, due in the main to meager and inadequate treatment.

An inspection of the nose revealed complete intranasal destruction, including the entire loss of the cartilaginous septum, with the exception of a slight vertical remnant anteriorly, which sustained the tip of the nose in something like its former position. The dorsum of the nose was entirely

depressed, giving that expression and appearance always suggestive of acquired or congenital luetic infection complicated by extensive intranasal destruction, and which is not only recognized by medical men, but likewise (whether rightly or wrongly) is often correctly interpreted by the general public; and thus not only is it a hideous deformity, but, in addition, it is often a source of reproach, making the unhappy individual display at all times a veritable badge of syphilis.

The material used in the case herein reported was a mixture of solid and liquid paraffin, one part of the solid to three parts of the liquid (American white vaselin), as suggested by Gersuney, having a melting point of 40°C. It was made sterile and was warmed by being placed in a receptacle of hot water just previous to the time of operation.

An antitoxin syringe was used as suggested by Heath of St. Paul, a Pravaz instrument as advised by Gersuney being found inadequate; the use of a large syringe also obviates the necessity of making repeated injections. Stress should be laid on the need of using a strong syringe of this kind, and the additional precaution should be taken of using an instrument having shoulders or eyelets, and of putting a new washer on plunger, since it takes a surprising amount of force to send onward the paraffin, which should leave the syringe in a worm-like thread. The ordinary antitoxin needle is too short, an aspirating needle works to a better advantage. It is entered at a point corresponding to the apex of the glabella, and passed onward toward the point of the nose, being kept as close as possible to the skin; it is withdrawn at the same time that the paraffin is ejected.

The molding of the mass in this case was quickly done, its solidification being encouraged by passing a small, smooth block of ice over the region. The patient returned to his home with instructions to make cold applications, and beyond a slight swelling

and some redness about the nose, no reaction of any note occurred. He expressed himself as greatly pleased, and was profoundly grateful for the work performed.

The quantity of paraffin used in this case was a little over two drachms, or the contents of an ordinary antitoxin syringe.

It was noticed during the operation that some blanching and cyanosis of the dorsum of the nose ensued, which occasioned some concern lest sloughing from pressure might follow; this fear, however, was soon dispelled by the tissues resuming their normal color. It might be well to remember, however, that strangulation is among the possibilities if too great a quantity is injected.

Meyer and Stein conducted a series of experiments on rabbits, dogs, and mice, with a view of determining the possibility of intoxication following injections of paraffin, and concluded that the possibility of such a result need not be reckoned with.

Pfannenstiel published a case of pulmonary embolism in a woman, in whom he injected paraffin around a vesicovaginal fistula, and he asserts that this accident was due to the paraffin. Gersuney and Moskowicz maintain, however, that its occurrence was chargeable to a breach of technique, as he injected the vaselin while it was still quite hot, and this hot liquid produced a thrombus by coagulation in a subcutaneous vein, with subsequent detachment of a part of the clot giving rise to the embolus. It may be said in confirmation that an embolus has never been observed in experiments made upon animals in which care was taken that the paraffin did not leave the syringe while it was hot.

Basing their observations upon experiments made on rabbits, Juckoff, Moskowicz, and Stein maintain that paraffin injected in this manner undergoes encapsulation, and that fibrous threads are formed throughout the mass. If this is true, we have a means of permanently relieving a class of nasal deformities which profoundly affect the happiness of the individual so afflicted.

The Prevention of Hernia after Laparotomy.—O. Wolff is of the opinion that the differences of opinion extant regarding the various methods of suturing the abdominal wall, the suture material used, etc., are without foundation, and that the cause of abdominal hernia must be sought for in some other direction. After having tried all the plans of suture proposed, and many kinds of suture material, with the result that hernia followed the operation in about the same proportion for all cases, he began to investigate further. An examination of his records showed that in every instance in which hernia occurred, meteorism had been present in the days following the operation. His theory accordingly is that the distention of the intestines strains the fascial layer more than any of the others, and that separation of these edges takes place, even though the skin wound remain intact. This may be the result either of the slipping of one or more knots, or of the cutting through of the sutures. It has, therefore, become his custom in any case in which, for any reason, he has to fear the advent of distention, as owing to the presence of even slight inflammatory conditions, injury to the peritoneum, etc., to forestall the occurrence of the complication by the insertion of a small strip of iodoform gauze into the angle of the wound for drainage. Only experience can determine just when and when not to drain, but since he has been carrying out this principle, abdominal hernias have become much less frequent in his practice, so that the slightly lengthened period of convalescence is more than compensated for.—*Centralblatt für Chirurgie.*

THE ARMY CARTRIDGE-BELT.*

By LOUIS L. SEAMAN, M.D., LL.B.,
NEW YORK.
LATE MAJOR AND SURGEON, 1ST U. S. VOLUNTEER.

THE *raison d'être* of this paper is to enter a protest, in the name of common sense and medical science, against the method of carrying the army cartridge-belt, as is practised to-day in our service in the tropics. To the ordinary observer this canvass belt, is most admirably adapted to the purposes for which it was designed. It is simple in construction, cheap, durable, comparatively light, and carries its load better than any other belt used by any other army in the world. Its clasp is easily adjusted; it stands wet and heat far better than leather, which in the tropics gets stiff, mouldy, and misshapen, and, from the standpoint of the Ordnance Department, it may be termed an ideal production. But the poor file who has to carry it, as well as his gun and various other accoutrements; how does it appeal to him? Unfortunately, where he is concerned, the exercise of brains in the Ordnance Department, as also in the Commissary Department, is in inverse ratio to the opportunities offered. There is a blunt old Anglo-Saxon saying, inelegant but nevertheless true, that "an army travels on its guts." Now, let us see how this applies to the cartridge-belt and its wearer in the tropics.

It may be conservatively asserted that fully 80 per cent. of all the troops serving in our insular possessions suffer at one time or another from some form of intestinal catarrh. I have seen as high as 75 per cent. of an entire command in this condition at one time. We will not discuss the causes that bring about this condition, whether, as I maintain, it results mainly from improper diet, or from the relaxation incidental to the extreme heat of the day, in contrast with the chill of the night; from impure water, or bacteria, or other causes; the fact still remains, that, as before stated, fully 80 per cent. of the men, at one time or another, suffer from this complaint. How is this condition met, and how would you treat patients in such a state? Would you apply to the most sensitive and unprotected portion of the entire anatomy, the abdominal region, to which nature has given no bony protection whatever, not even as much as a floating rib, but has depended solely on the single support of the spinal column, and the flabby abdominal walls, I say, would you apply to an irritated and inflamed intestine an unsupported belt weighing ten or twelve pounds? The effect of wearing such a belt, assuming the point of rest as the center of the spinal column, is to create a pressure over the abdominal cavity, changeable with each step the wearer takes. This intermittent action is a practical massage of the intestines, which creates peristalsis, and is one of the most efficient methods of exciting intestinal action. The first principle of treatment of any form of intestinal catarrh is rest; and pressure of any kind is detrimental. This heavy load over the abdominal cavity produces local hyperæmia, thereby creating a fruitful culture ground for bacteria. Two of the greatest dangers to be apprehended in the tropics are the presence of bacteria and a fruitful ground for their development. The strongest microbe falling on barren soil is comparatively harmless, the weakest falling on ground ripe for its growth instantly becomes a source of danger. The unsupported cartridge-belt assists largely in the creation of one of these dangerous factors.

In no other army in the world is this heavy weight

*Read before the meeting of the Association of Military Surgeons of the United States, 1902.

carried from the waist band. All support it by one device or another from the shoulders, and yet I have been on a "hyke," and heard an officer severely reprimand a soldier, who, almost doubled up with intestinal cramps, had dared without consent to sling his belt over his shoulder to obtain a little temporary relief from the pains it was creating. Yes, and I have also seen 82 per cent. of an entire Division temporarily invalided in a single day, and one of the greatest factors in bringing about this disaster, next to the intense and agonizing heat of the Philippines was, in my opinion, this same unsupported cartridge-belt.

Thus does the Government, which, by every law of humanity, is bound to protect its guardians by the best hygienic surroundings, compel them to submit to the causes which superinduce and aggravate the very diseases which are filling our army hospitals. A continuance of use of this belt in the tropics is a slap in the face of the goddess of Hygeia, and an insult to the intelligence of the age, and, in the name of this association, I ask that a protest be entered against its further use when relief may be obtained by its suspension from the shoulders by some of the methods advocated by the able officers who have given it their careful study.

247 Fifth Avenue.

The Intracellular Glycogen Reaction of the Leucocytes.—S. Kaminer considers that the intra- and extracellular glycogen reactions in the blood, first described by Ehrlich in 1883, are different in nature and require different interpretations when found. The two reactions appear sometimes singly and sometimes simultaneously, and a common source for both does not, therefore, seem possible for all cases. A large part of the so-called extracellular glycogen is probably nothing more than an artefact, and there is also a possibility that another portion is identical with the blood plaques. The extracellular reaction has been observed in normal blood by all authors, except Czerny, while the intracellular reaction has been found only in disease. The author's own experiments also show its absence in the blood of goats, dogs, rabbits, guinea-pigs, mice, chickens, and pigeons. In pus both reactions occur constantly. The observations on the occurrence of iodophilia already published have been greatly lacking in the absence of systematic autopsy records, and, therefore, in many cases the reaction has been imputed to conditions which were accompanied by it only through chance as the result of a complication. Livierato's investigations show that in man it is most pronounced in croupous pneumonia, the intensity of the reaction standing in direct relation to the height of the temperature, and the extent of the pneumonic process. Similar results were obtained in pulmonary tuberculosis and the acute exanthemata. It is absent in articular rheumatism, in chronic afebrile and non-inflammatory conditions, such as heart and liver lesions, and, what is of importance, in typhoid fever, when unaccompanied by pulmonary complications. In endeavoring to trace the cause of the reaction, the author considers (1) fever; (2) leucocytosis; (3) bacterial poisons. The first two he throws out, because both of these conditions frequently exist without the presence of the reaction, and then recounts the results of an extensive series of experiments on animals infected with various bacterial and other poisons. These show that the reaction may be brought about by the poisons of the streptococcus, staphylococcus, bacillus pyocyaneus, diphtheria bacillus, anthrax bacillus, bacillus Friedländer, pneumococcus, typhoid bacillus, bacterium coli, and such toxin-like bodies as ricin and abrin.—*Zeitschrift für klinische Medicin.*

Observations on the Proportions of the Leucocytes in the Blood During Pregnancy, Labor, and the Puerperium.—Carl Hahl has undertaken a series of investigations to determine the changes occurring in the number of leucocytes in pregnancy and during the puerperium, and has arrived at conclusions differing somewhat from those of other observers. These of themselves are sufficiently discrepant to indicate the need for a careful study of the subject, and the author's figures are reported in sufficient detail to make them an interesting contribution to the statistics of the question. The thirty-six patients examined ranged from nineteen to forty-three years in age and comprised 21 primiparæ and 15 multiparæ. Toward the termination of pregnancy a slight increase in number of leucocytes was constantly observed, though this never exceeded 10,000 to the cubic millimeter. No difference existed between primiparæ and multiparæ. With the onset of labor a marked hyperleucocytosis sets in, the numbers increasing up to 10,000—20,000 per c.m., and even in one case to 30,000. The average figure for primiparæ was 15,380; for multiparæ, 12,940. Age had no influence. During the puerperium this hyperleucocytosis gradually subsides, and within a few days, usually before the termination of the first week, the blood count is normal again. The leucocytosis is essentially polynuclear, the mononuclears being relatively increased, though their absolute number is unchanged, while the eosinophiles are absolutely and relatively diminished during the period of hyperleucocytosis, to undergo increase in both respects when the total count has returned to normal. The number of most cells is unaffected. In considering the causes of this change in the composition of the blood the author calls attention to the fact that it appears to be the setting in of the pains which determines the increase, and inasmuch as counts made in blood taken from the cervix showed a higher proportion of leucocytes than those made from the peripheral circulation, he believes that the uterine contractions may force quantities of the cells out into the circulation. At the same time the existence of some chemotactic agent in the blood is assumed to account for the stimulation of the leucocyte-producing organs.—*Archiv für Gynäkologie.*

The Treatment of Rheumatoid Arthritis, with Especial Reference to the Specific Action of Ferrous Iodide.—J. R. Clemens says that syrupus ferri iodidi, one drachm, thrice daily, given over a period of two or three months, will not only remove the pain from the joint, but will also cause the total disappearance of crepitus. During the administration iodism may necessitate diminishing or withholding the medicine for a time. The patient, usually a woman of middle age, comes complaining of neuralgic pains in a shoulder joint, and will tell you that she is gouty or that she thinks the trouble is rheumatic. The pain is essentially neuralgic, starting in the shoulder, and following down the course of the nerves that supply the hand and fingers, with tingling and numbness of the latter. On examination typical Heberden's nodes are seen. In the presence of these nodes a more favorable prognosis of the shoulder trouble may be given. The treatment, in addition to the iodide of iron, should include a generous dietary. Douches and local applications to the joint are contraindicated, as are medicated hot baths. If the pain is very severe, sodium salicylate may be exhibited as a symptomatic treatment.—*The Therapeutic Gazette.*

The Heredity of Synovial Ganglia.—Ch. Féré reports the case of a woman who was affected with ganglion of the wrist. Her descendants in three generations consisted of eight girls and nine boys. Six of the girls and one boy were affected in the same way as the first case. In a number of these patients the tumor made its appearance after brusque, if not violent, movements, which allows the inference that it was occasioned by rupture due to enfeebled resistance of the synovial membrane. This defect in the synovial membrane may be compared to the defective resistent power of the aponeuroses often observed in persons belonging to a neuropathic family.—*Revue de Chirurgie.*

TYPHOID FEVER AMONG ARMIES IN THE FIELD.

TYPHOID fever, in every war that has been waged since the time when armies were first formed, has been one of the chief causes of sickness and death among the combatants. Indeed, in most wars, the disease has been responsible for the greater part of the death rate, and, in many campaigns, has killed more persons than other maladies and bullets combined. Typhoid fever may be truly termed the scourge of armies. With increased knowledge of sanitation, there has been little or no corresponding progress made in the means of prevention or control of typhoid fever among soldiers. The Spanish-American and South-African wars are the most recent and most conspicuous examples in point. In the first named, soldiers died like flies from the disease in many of the camps of this country—mainly owing to neglect of ordinary sanitary precautions by the authorities, while in the South-African campaign the mortality and invaliding from this cause were appalling, and cast serious reflections upon the organizing capabilities of the British War Office. The claim is made that if that Department had harkened to and heeded the advice freely tendered by experienced military medical authorities, and had employed experts whose duty it would have been to look after the physical well-being of the troops from a sanitary standpoint, the death rate must have been considerably lessened.

All, however, was subordinated to the exigencies of the military situation, and sanitary matters—which, if not so obviously important, are at least worthy of some consideration—were almost entirely neglected, with results that were both historic and disastrous. The old adage, "experience teaches," does not seem to apply in the case of war and typhoid fever.

Dr. H. E. Leigh Canney, writing to the *Lancet* of December 27, on the subject, enters fully into the question of typhoid fever in armies.

Referring to flies as conveyers of the infection, he says: "That flies can give rise to an epidemic of typhoid fever in a camp with proper earth treatment of the excreta, even if one or two cases of typhoid fever were present, is extremely improbable, unless it were done by infection of milk or large quantities of water. Without these agencies only a few sporadic cases would possibly result. I therefore prefer to consider flies as vehicles for the possible conveyance of typhoid bacilli to man, as a water avenue mainly." Again, he says: "Enteric fever will have to be met and overcome, in no matter what part of the world, on the water-borne theory mainly, though every other avenue must also be guarded." As to the validity of the reasoning or evidence in support of the air-borne theory of the spread of typhoid fever, Dr. Canney thinks it will not bear the test of close investigation.

The writer comes to these conclusions: (1) That unless all the water avenues to an army or camp have been protected, it cannot be assumed that the incidence of typhoid fever is due to air-borne agencies. (2) That it is not possible to affirm that the water avenues to an army are closed unless the sterilization and distribution of the water are carried out by specially-trained men. (3) That the evidence of air-borne typhoid fever is not clearly established in recorded Indian military experience. (4) That in South Africa and Egypt the evidence is opposed to this theory. (5) That the weight of evidence from India, Egypt, and South Africa is immensely in favor of the paramount importance of the water avenues, especially if in the onset of the epidemics, and that the spread of the disease by the subsidiary avenues—flies, dust, and contact—only becomes a factor of importance under conditions of the grossest neglect of sanitation. (6) The evidence from Egypt proves that if the water avenues are protected, all other avenues are powerless to originate and to spread epidemics of typhoid fever in large bodies of men.

Dr. Canney makes a strong plea for the appointment of army medical officers specially trained in sanitation.

In these times, when science has wrested from so many diseases the secret of their origin, and has, in some instances, provided preventive and curative treatment for them, it seems a grave blot on the page of advance that, through avoidable neglect, a disease like typhoid fever should be allowed to spread almost unchecked through masses of men. With regard to the cause of the disease, investigations undertaken up to the present demonstrate that water is by far the most important factor in originating and spreading typhoid fever. The conclusions reached, with respect to the part played by flies and dust in its dissemination are not, as yet, sufficiently definite to pass an authoritative opinion. But on one point there is a remarkable unanimity of views, that, by good sanitary measures, typhoid fever can be both prevented and controlled in armies. The suggestion, therefore, put forward by Dr. Canney, that medical officers specially trained in sanitation should be appointed to armies, might, it will be thought, find favor in all civilized countries.

THE CHASTE CARE OF FEMALE PATIENTS.

MR. WEMPLE has introduced in the Assembly a bill relating to "the treatment and care of female patients in hospitals and elsewhere for the protection of the honor and morality of such patients," which has some remarkable and ridiculous provisions from a strictly medical point of view. It is evidently founded on the presumption that the physician or surgeon in attendance upon a case is often

guilty of indecency and immorality and that it is time to check such reprehensible proclivities. The measure carries defeat on its face in view of the utter absurdity of the position taken. How the necessity for the passage of the bill can be made apparent is past belief. Its inception is an open insult to the profession and should be duly resented by every honest physician throughout the State.

In the interests of a free discussion of details we give herewith the Wemple bill in full:

"Section 1. That it shall be unlawful for any student, attendant, house physician and surgeon, or anyone else, to expose the body or person of any female patient, in any hospital, medical college or elsewhere, in the State of New York, for any purpose other than the performing of an operation necessary for the recovery, or relief from pain, of said female patient.

"§ 2. That when it shall be deemed necessary for such operation to be performed, the parents and sisters and brothers, or such of them as shall be living, or in case none shall be living, the guardian or next friend designated by such patient, shall be notified, at least twenty-four hours before the performing of such operation, and at least three of such persons so notified shall be allowed to be present in the operating room, during the entire performance of such operation, and until said patient shall be removed from said operating room and replaced in her bed until she recovers her sense; except, when in case of accident the notification herein required may be dispensed with, if an immediate operation shall be deemed necessary by the authorities in such hospital or medical college. In case such notification shall be dispensed with no person or persons other than immediate relatives or guardians or next friend of such female patient so to be operated upon, shall be permitted to witness such operation or any part thereof.

"§ 3. Any person or persons convicted of performing, or attempting to perform, or who aid by their presence or otherwise in the performing of an operation upon a female patient, except as permitted herein, shall be deemed guilty of a felony, and the punishment thereof shall be by a fine of not less than one hundred dollars, and not more than five hundred dollars, or by confinement in a county jail or state prison for a term not less than one year and not more than five years, or by both such fine and imprisonment.

"§ 4. This act shall take effect immediately."

In the name of all that is reasonable or just to physician or patient how are the provisions to be carried out consistently with the pretentious decency of the reformer. Of what possible use can be the attendance of a male or female non-professional person at an operation on a female other than the gratification of an idle curiosity which is the more reprehensible in proportion to its alleged necessity. Certainly the fewer the number that may be called upon to witness a warrantable exposure the better for all concerned. And shall it impliedly mean that any relative shall object to certain procedures which the operator may decide as best suited to his purposes? While science knows no sex or condition in its fight for life and the relief of suffering, what can be said for the good taste or decency of a brother, father, or, perhaps, male guardian being present at a forceps delivery, a hysterectomy, or an operation for hemorrhoids? Has the patient herself nothing to say on the subject?

In urgent cases, when notification of relatives is impossible, it is provided that none but the operator and his assistants shall be present, thus excluding from the operating-room all medical students and physicians who might be benefited by the clinical experience in the case.

If it were necessary to allude to more absurdities of the Wemple bill reference could be made to the provision that no exposure of a female patient can be made anywhere in hospital, college, or private office for purposes of diagnosis, unless, perhaps, the family of the patient groups itself around the examining chair. All this because the doctor must, according to the new law, be trusted no farther than a common moral leper and an ordinary and designing blackguard. May it not be possible that the physician has still enough honor in his own keeping to resent the ignominy of such a foul and dastardly imputation of his purely professional motives. There is not a medical man in the State who will not defy the Assembly Committee to report this bill and who will not challenge its right to recommend its passage.

THE MEDICAL PROFESSION AS A CAREER.

Dr. D. B. St. John Roosa gave, in the *New York Tribune*, January 18, an exposition of his views as to the best training for a youth, to fit him for the practice of medicine. A primary and essential qualification is, thinks the author, the possession of a sound mind in a sound body, while the highest standard of morals is also required of him who aspires to a place as a physician. No man is fit to take the sacred responsibility of the care of the body of another human being, a body which is the temple of the soul, or to be entrusted with the personal history of his patient, unless he has the qualities of reticence and a high sense of honor, added to a kindly tactful disposition.

Dr. Roosa then very properly insists upon the importance, nay, the necessity of a young man having given satisfactory evidence by means of an adequate test examination, that he has a sufficient knowledge of general subjects. He should have some knowledge of Latin and Greek, and know enough of the English language, geography, and history to enable him to enter the freshman class in such a college as Amherst, Union, Oberlin, or the like, and then to pass the full period of four years in such a college. As to taking up special subjects relating to medicine before entering upon the medical course proper, the writer is of the opinion that this procedure is unnecessary, but deems a thorough knowledge of French and German of the highest value.

However, the ante-professional curriculum mapped out above is the ideal one, and of course is not absolutely necessary to the making of an excellent medical practitioner. Greek and Latin, Dr. Roosa holds, are necessary to the comprehension of anatomical terms, and should be learnt by youths intending to enter the medical profession.

The early medical education of an American student should take place in his own country, and he should not go abroad for the purpose of medical study, except to add the "coping stone" to the foundation and structure laid and builded here. The author also thinks that didactic lectures will ere long be things of the past, and that the teaching of the future will be above all, practical. A well-

deserved tribute is paid to the uses of post-graduate schools.

Referring to the rewards which the medical profession offers to its votaries, the writer is naturally not unduly optimistic. The medical course is an expensive one, and the competition in the profession is nowadays exceedingly acute. The physician in this country has a good social position, but, as a rule, in the beginning he cannot expect to make more than his bread and butter. He may enter the army or navy, become an examiner to an insurance company, or make a bare livelihood by writing for the medical journals, but, as Dr. Roosa points out, ambitious young men, who are well prepared, often prefer to endure hardship for a season in waiting for practice than to accept these positions, which are, on the whole, less satisfactory to a man with aspirations than the avenues opened in hospital or dispensary, joined to poorly paid and scanty private practice.

With regard to ultimate financial success, the writer remarks that it is very difficult to make comprehensive statements. While a practitioner of medicine will be able, in almost any community to have the comforts of life, so far as his time will allow him to enjoy them, he will very rarely gain great wealth, however high his position may be. Medicine is no career for those whose object it is to amass money; honor may be had, and fame is within the reach of the scientific medical man, and the profession is perhaps, beyond all others, a useful, honorable, and dignified calling.

The great drawback to the practice of medicine in this country—and to this phase of the matter Dr. Roosa makes no allusion—is the sharp and increasing competition brought about by the lack of a uniform standard in all the States of the Union. More medical graduates are turned out each year than there are patients on whom to practice, with the chance of gaining a good livelihood. If a uniform high standard of medical education were adopted throughout the country, the output of medical men would be less, competition would be diminished, and on the whole the result could not be but advantageous to all concerned.

CONDITIONS AT BELLEVUE HOSPITAL.

The city hospitals of New York during the past four years have been at intervals severely criticised for their inefficient management. This has been especially the case with Bellevue, and although many of the accounts which have appeared from time to time in the lay journals regarding instances of gross maltreatment of patients within its walls may have been exaggerated, there can be little doubt that such tales were founded more or less upon solid facts. That the system in vogue in the city hospitals is faulty, the officials themselves have freely allowed. So much so, indeed, that an influential and representative Board of Trustees, under the chairmanship of Dr. John W. Brannan, instituted some few months ago a careful and searching inquiry into the whole matter, and recommended certain measures of reform which it was declared would place the city hospitals upon a proper footing. At the time when the Board of Trustees published its report and recommendations, the Medical Record took notice of them editorially, and stated that if the suggestions proffered by this body were carried out to the letter there would be little with which to find fault in the management of the city institutions for the sick and injured.

Of course, it could not be expected that all the reforms would be carried out at once, but it was anticipated that some of the most crying evils would have been remedied as promptly as possible. However, according to a recent occurrence at Bellevue, it appears that but meagre progress has been made in the reorganization scheme. It is true that the Board of Trustees has issued resolutions in which its members assert that after the most searching investigation no evidence can be discovered in support of the present charges of cruelty to patients, and state their strong belief in the innocence of the nurses, but the fact remains that, as heretofore, these nurses are paid paltry salaries, and are not fitted by training and experience to have the charge of sick persons.

As pointed out in the Medical Record on many occasions, Bellevue and its allied hospitals must be reformed root and branch and not merely tinkered with. Complete new modern buildings, thoroughly equipped, are required in the place of the present ramshackle, incongruous, and inconvenient collection of fabrics now known as Bellevue. Thorough reorganization of the entire system of management, and especially of the nursing staff, is a prime necessity in the reform of the city hospitals. Such institutions in a city of New York's size and wealth ought to be a source of pride to its inhabitants rather than, as now, a cause for shame. The Board of Trustees will have the moral support of the community at large if it will continue to urge upon the Mayor and his advisers the absolute need of its excellent recommendations of last summer being carried out in their entirety.

It is certain that the pressure of public opinion—induced by the constantly recurring reports of scandals in the city hospitals—will eventually compel the present apathetic municipal authorities to "sweep and garnish" these institutions.

A Handy Method of Sterilizing Instruments.

Dr. Karl Gerson describes in the *Deutsche medicinische Wochenschrift* an efficient and simple mode of sterilizing instruments. Professor Mikulicz brought into use some time ago the method of sterilizing the hands before performing an operation by means of friction with spirits of soap. As a sterilizing agent for the hands the spirits of soap acted well.

Dr. Gerson has recently tested the efficiency of the same method, and has proved to his own satisfaction that instruments rubbed with cotton wool moistened with a solution of spirits of soap are effectually sterilized against the most virulent germs, and that by wrapping them in cotton wool wetted with it they will retain their aseptic condition for a length of time. By applying the spirits of soap thus, the spirit evaporates, leaving a coat of soap on the instruments while the substance adheres to the wool throughout.

Dr. Gerson goes so far as to declare that such are the remarkable antiseptic properties of spirits of soap, that in the case of bougies, catheters, and other large instruments, which it might be difficult

to wrap in cotton wool, a rubbing with spirits of soap for three minutes before an operation fully answers the purpose.

The Hospital, December 6, commenting upon this statement, says that it alone is enough to throw doubt upon the whole of Dr. Gerson's conclusions. The writer in the *London Journal* goes on to say: "The septicity of a foul catheter lies within, and it must be quite impossible to sterilize such an instrument with certainty by means of any solution, however germicidal it may be. It is here that heat has the pull, penetrating as it does into the joints and corners of the most complicated apparatus. Still, for solid and smooth instruments there is every reason to believe that the application of spirits of soap will be useful. A somewhat lengthy experience has shown that it does very well for the hands, which are much more septic than any well-cleaned instrument, and there would seem to be no ground for doubting that it will do equally well for any solid instrument to the whole surface of which it can be directly applied. Spirits of soap, it may be added, is merely hard soap dissolved in dilute alcohol. It is essential to remember, however, that for the removal of the coating of soap left upon the instruments, sterilized water or spirits of wine and sterilized lint, or other form of 'wipe' must be employed, so that, after all, even by this method, one does not get rid entirely of sterilization by heat."

The foregoing remarks are very much to the point, and there can be no doubt that heat by either boiling or steaming is the best sterilizing agent known. Nevertheless, there are times when the facilities for these processes are lacking, and when a more simple method would be very convenient. It is upon such occasions that the method advocated by Dr. Gerson should be extremely useful.

One cannot refrain from moralizing to some extent when one considers how ideas as to the most efficient means of sterilization have become modified. Of course the principle laid down by Lister has remained the same, but the elaborate antiseptic methods which, after his immortal discovery became the vogue, and which, in many places, were carried to absurd lengths, have almost died out, and now the most scrupulous cleanliness, combined with boiling or steaming, is generally recognized as affording after all the soundest defence against infection. The late Lawson Tait who, despite certain eccentricities, was endowed with a very large share of shrewd common sense, was one of the first surgeons of world-wide reputation to laugh at the vagaries of the ultra antiseptic clique, and to assert that extreme cleanliness and boiling water was more effective than the preparations which some operators used to make before commencing their work.

Duplication of Fears in Twins Widely Separated.

Ch. Fere reports, in the *Comptes Rendus de la Société de Biologie*, a curious case of the approximately simultaneous development of similar fears in twins living remote from each other, the exciting cause being apparently a fright to one of them. The twins, females, were of a neuropathic family on the mother's side. They resembled each other singularly closely, even to an almost exactly duplicated birthmark; also physiologically and psychologically (voice, articulation, expression, walk, attitude, holding of pen or needle; certain repugnances and preferances, such as a marked state for salt, and repugnance, to the point of vomiting, for butter; sympathies and antipathies for persons and animals; and appreciations of colors and odors). The mother dying a few days after their birth, each of the twins was taken by an aunt, reared by a separate nurse, and brought up differently, along with its cousins, male and female. Up to six years of age they saw each other often. Then one aunt removed from the country, and thenceforth their communication was limited to a few words added to the letters of the aunts. Menstruation appeared in each at thirteen years and three months, three days apart. Four months later A. was frightened by a carriage passing rapidly near her. There, however, appeared to be no immediate results. Menstruation appeared at the normal time, the second day after, without apparent trouble. The day of its cessation, however, at supper, on wishing to drink, she put down her glass suddenly, with fright, saying there must be fragments from the rim of the glass, this rim could wound her, there must be fragments fallen to the bottom of the glass. It seemed impossible for her to use this glass, and a silver cup was given her instead. Little by little she came to examine the bottle, fearing that there were fragments of glass which had fallen to the bottom, and had not been emptied, and she would drink only when the glass bottle was nearly full. When this singularity was reported to the family where the other twin (L.) lived, attention was directed to a singularity which had existed several weeks in her; she did not empty her glass completely, but threw out what remained at the bottom before refilling it. Questioning was avoided, and things remained unchanged for a fortnight, but, following a rather grave angina, the fear acquired a considerable intensity, and extended from fear of swallowing glass to fear of touching it, and fear of glass objects and of objects resembling glass; and, some months later, to the inability to speak of glass objects without visible repugnance. Meanwhile, with A., the fear of swallowing glass has remained, and she wipes her hands after touching it. Interesting as the case is, it can, however, hardly be said to satisfy the demands of modern psychiatry, as it lacks a sufficiently detailed study, or, at any rate, report.

An Inebriate Act.

The question of checking the wide-spread consumption of alcohol which prevails to a greater or less extent throughout the world, is one which is profoundly impressing thoughtful men of all civilized nations. It has now been demonstrated with a sufficient degree of accuracy that alcohol does little if any good to a human being even when used as a medicine, while there are some who assert that it is under all conditions a poison and not a food. Be this as it may, the fact is undoubted that alcohol used to excess is one of the most harmful agents of evil known to man, and is responsible for a large proportion of the sickness and suffering everywhere existing. In this country the drink question does not obtrude itself so insistently as it does in most of the countries of the old world. In Great Britain particularly, the inroads made on health and prosperity by drink has alarmed the community to such an extent that law-givers and philanthropists are alike eager to find means to curb its progress. An inebriate act was passed about a year ago, by which it was enacted that hopeless drunkards might be consigned to an institution—under certain conditions—wherein they would be treated and, if possible, cured of their infirmity.

The report of Dr. Welsh Brantwaite, inspector

under this act, has recently been made public, and treats of many details with regard to the retreats established under this act. Among much interesting matter the report strongly upholds the prevalent opinion, that it is useless to detain a drunkard for short periods, that is if a cure is desired. Abstinence from alcohol for a term of at least twelve months is necessary if permanent good is to be effected. A drunkard, as a rule, exemplifies in his habits those attributed to the devil in the old saying, "When the devil was sick, the devil a saint would be; when the devil was well, the devil a saint was he." It is much the same with the drunkard. When he has been on a protracted debauch, and feels really sick, with nerves out of gear, fear brings remorse, and at the time he feels that he loathes drink, and would be glad to go anywhere where he might be quiet and "far from the madding crowd." However, when his stomach recovers its tone, and his nerves get strong again, and he is not afraid to once more look his fellow man in the face, he forthwith forgets his good resolutions, and frequently the last state of that man is worse than the first. For such a one a lengthy stay in an institution is essential.

Dr. Brantwaite makes some recommendations with regard to provision needed. He suggests that institutions should be provided which might serve as a refuge for a drunkard who was especially uncontrollable in his actions. Such individuals, although often more able to earn a good living than their sober brethren, are, when they lapse from virtue, generally a terror and disgrace to their families and relations, and a nuisance to their friends. Nevertheless, there is no place in which to put them, as neither a hospital nor a lunatic asylum is a fitting resort for them.

The *Hospital*, January 3, referring to the subject, says, "There can be little doubt that, as Dr. Brantwaite suggests, there is room for institutions in which patients might be received who, although able to sign for short periods, would utterly refuse to submit to prolonged detention. These short period retreats, although hardly aiming at cure, would be an immense convenience to friends and relatives, and in a certain but probably small percentage of cases they would give to the incipient drunkard—especially to such as have taken to drink under the stress of some temporary trouble—that which one would always be glad for even a criminal to receive, another chance."

It will be instructive to watch the working of the British Inebriate Act, the time of its existence has not yet been long enough to learn much from it, but America may one day need laws to check the spread of drunkenness, and may then be glad to turn to the old world for the knowledge of how best to frame and carry out restrictive legislature.

Drug Adulteration and Substitution.—The Board of Health intends to proceed against 315 druggists of the Boroughs of Manhattan and Brooklyn who, the inspectors have discovered, are in the habit of selling adulterated phenacetin. It was discovered a short time ago that a phenacetin powder bought in a drug-store was adulterated, and from this arose the suspicion that other druggists might be doing the same thing. Therefore, a force of inspectors was sent out to visit drug stores in the two boroughs. Of 373 samples obtained 315 of the powders were found to be impure. In some cases the powders contained no phenacetin at all.

News of the Week.

Another Tuberculosis Serum.—It is reported that Dr. Marmorek, a Viennese bacteriologist, working at the Pasteur Institute in Paris, the discoverer of an antistreptococcus serum, has succeeded in elaborating an anti-tuberculosis serum of proved efficacy. The discovery of the serum was made, it is said, nearly a year ago, but the announcement was delayed until a sufficient time had elapsed for a thorough and satisfactory trial of the remedy.

Burning of a Smallpox Hospital.—The city pesthouse of Biddeford, Me., was burned early in the morning of January 26. The patients were in no danger from the flames, but they suffered severely from exposure to the severe cold, none of them having suitable clothing for outdoor use, and the thermometer marking a zero temperature.

Dr. Luther H. Gulick has been appointed by the Board of Education director of physical training for the public schools of New York city. Dr. Gulick is a graduate of the New York University Medical College in 1889, and is one of the leading physical educators in the country.

Hospital for Manila.—It is reported that Bishop Brent of the Philippines, late of Boston, is at the head of a movement to establish a large non-sectarian hospital in Manila, which is to be modeled after the Boston City Hospital. The government has been petitioned to aid in this undertaking, which, under present conditions, could not be supported by private effort.—*Boston Medical and Surgical Journal.*

Western Ophthalmological and Oto-Laryngological Association.—The eighth annual meeting of this society will be held in Indianapolis on April 9, 10, and 11, under the presidency of Dr. William L. Ballenger of Chicago. The secretary of the association is Dr. Derrick T. Vail, 22 West Seventh street, Cincinnati.

The American Medico-Psychological Association.—This association has recently become affiliated with the Congress of American Physicians and Surgeons, and must, therefore, meet with the other societies forming the congress. The place of meeting for this year is consequently changed from Providence to Washington, the date being fixed for May 12, 13, 14, and 15. The secretary of the association is Dr. C. B. Burr of Flint, Mich.

Charges of Cruelty against Bellevue Nurses.—Eight of the male nurses and attendants at Bellevue are to be brought to trial for alleged cruel treatment of a patient in the alcoholic ward of the hospital. After a careful investigation, the Board of Trustees of Bellevue and the allied hospitals adopted a resolution that it had discovered no evidence in support of the charges, but, on the contrary, very strong evidence tending to disprove the charges in every detail. The board therefore decided to employ counsel to defend the accused nurses.

A German View of Hypnotism.—A commission, consisting of Prof. E. Mendel of Berlin, Drs. Munter, Aschenborn, and others, which was appointed about a year ago by the Prussian Minister of Education to investigate the therapeutic value of hypnotism, has just concluded its labors. The report, which was recently published, declares that hypnotism cannot produce organic changes, nor cure epilepsy or hysteria, but it can be used helpfully in some instances by removing symptoms through suggestion. The influence of suggestion upon patients cannot be left out of account in any rational system of treatment, but hypnotic suggestion, the commission asserts,

may intensify disease when laymen apply it who do not know when to use it and when not to do so. The influence of hypnotic suggestion diminishes, also, the report continues, in proportion to popular knowledge of it. It is most powerful when regarded by a subject as marvelous and supernatural.

Jewish Hospital Association Convention.—The annual meeting of the National Jewish Hospital Association took place in Denver on January 25 and following days. The sessions were held at the Jewish Hospital for Consumptives, an institution founded by the association, and, though non-sectarian, supported by contributions raised by the association. The feature of the opening session was the dedication of the Guggenheim Pavilion at the hospital, which was built by the Guggenheim Brothers of New York at a cost of $35,000, and presented to the association. Simon Guggenheim of New York made the speech of presentation.

Popular Lectures on the Physiology of the Nervous System.—Dr. John G. Curtis, professor of physiology in Columbia University, will deliver eight illustrated lectures in the great hall of Cooper Union on Mondays, February 9, 16, 23, and March 2, 9, 16, 23, and 30, at 8 P.M. The following are the titles of the lectures: (1) How We Know that the Brain Is the Seat of Feeling, Thought and Will; (2) How the Nerves Work; (3) How the Muscles Work; (4) How We See; (5) How We Hear; (6) Taste, Smell, and Touch; (7) The Involuntary Workings of the Nervous System; (8) How Our Bodies Keep Their Balance.

Trouble in the Red Cross Society.—A memorial, signed by twenty-two members of the executive committee of last year, has been presented to Congress, protesting against the control of the Red Cross by its president, Miss Clara Barton. The memorial says that formerly there was provision that the annual meeting should be held in Washington at a fixed time, while under the new arrangement power is conferred upon the executive committee to call this meeting if it chooses at remote places and inconvenient times. Another section provides that the president may be elected for life, and almost unlimited and uncontrollable powers are conferred upon that officer. Miss Barton has been elected under this provision. It is also pointed out that she has power of appointing the executive committee, of which she is a member, and to which is intrusted the general administration of affairs. The objection is also made that authority is given her to ignore the vice-president in case of her own sickness or absence, and appoint any one president *pro tem.* with full power. Attention is also called to the fact that in times of emergency and sudden disaster the contribution of funds under the new by-laws would not pass through the hands of the treasurer, and that no provision is made for auditing accounts.

The Army Medical Service.—Examinations of candidates for appointment in the Medical Corps of the army will be resumed by the Army Medical Board in Washington on April 20, next. Classes will be invited to appear on April 20, and each Monday thereafter so long as is necessary. Full information as to method of application, nature and scope of examination, etc., will be furnished by the Surgeon-General's office upon request of those interested. Applicants from civil life are restricted in age to twenty-nine years, and hospital training or professional experience in private practice is expected of all candidates. There are at present thirty-five vacancies to be filled.

New College of Pharmacy in Brooklyn.—The formal opening of the new building of the Brooklyn College of Pharmacy took place on January 29. The new college is built of Samson brick, with Indiana stone trimmings and a stone portico. There are three stories besides the basement, and the building proper is fifty feet wide by ninety feet long. In addition to a library, a recreation room and a coat room, the building contains a main lecture room, with seating capacity for 200; a chemical laboratory, with accommodations for 200 students at a time; a pharmaceutical laboratory, which will accommodate 170; a stock room, a pharmacognosy laboratory, and two large quiz rooms.

Burning of a Lunatic Asylum in London.—Early in the morning of January 27, fire broke out in the Colney Hatch Lunatic Asylum, London, and destroyed some large wooden buildings accommodating 350 patients. In spite of the labors of physicians and nurses, fifty-four of the women patients were burned to death.

Consumption Cures and the Tuberculosis Committee of the Charity Organization Society.—This committee has recently adopted the following resolution relative to consumption nostrums:

Whereas, It has come to the knowledge of the Committee on Tuberculosis of the Charity Organization Society that many so-called specific medicines and special methods of cure for tuberculosis have been and are being exploited and widely advertised, and

Whereas, The advertisements of some of these cures have made such reference to the Tuberculosis Committee of the Charity Organization Society, or to some of its members, as to create the inference that this Committee, or its members, recommend or advocate the use of many such so-called specifics or special methods of cure for pulmonary tuberculosis, or consumption, and

Whereas, There is no specific medicine for this disease known, and the so-called cures and specifics and special methods of treatment widely advertised in the daily papers are in the opinion of the Committee without special value, and do not at all justify the extravagant claims made for them, and serve chiefly to enrich the promoters at the expense of the poor and frequently ignorant or credulous consumptives, therefore,

Resolved, That a public announcement be made that it is the unanimous opinion of the members of this Committee that there exists no specific medicine for the treatment of pulmonary tuberculosis, and that no cure can be expected from any kind of medicine or method except the regularly accepted treatment which relies mainly upon pure air and nourishing food.

A Shellfish Scare in London.—The English oyster—a miserable creature at its best—is said to be everywhere so thoroughly seasoned with typhoid bacilli that its consumption by man has almost ceased. A despatch to *The Sun* states that Dr. Collingridge, the chief medical officer of London, has issued a report in which he announces that all of the Thames fisheries, including the estuary, are contaminated with the bacilli of typhoid fever. His condemnation includes the famous Whitstable oyster beds, where 20 per cent. of the oysters examined were found to be infected. A ban has also been pronounced against whitebait, shrimps, smelts, and cockles. Contamination by sewage was found fifty miles away from London, while an even worse state of affairs exists at other points on the English coast from which shellfish, etc., are supplied to the markets. The infection in those cases is due altogether to bad local sewage. There have been other fatal warnings since the terrible Winchester banquet, where the eating

of oysters, it was said, spread death in that neighborhood. These include three deaths from enteric fever in one London family, due to the eating of cockles. The shellfish trade has already been seriously crippled by the effect of these fatalities, and it will probably be practically destroyed by Dr. Collingridge's report. The question will, it is said, be made the subject of a Parliamentary inquiry.

More Anti-Osculation Legislation.—Another foolish attempt at sanitary legislation is reported from Minnesota, where a bill has been introduced in the Legislature declaring that it shall be unlawful for one person to kiss another unless it can be proved that he or she is free from contagious or infectious diseases. Violation of the law is declared to be a misdemeanor, punishable by a fine of from one to five dollars for each kiss.

Typhoid Fever is reported epidemic in Ithaca, N. Y., where there are at present over two hundred cases. The City Hospital is overcrowded and even the nurses' quarters have been converted into wards for the reception of patients with the disease. The authorities urge the boiling of all drinking water.

Health Day in Illinois.—There is hope for Chicago if a certain scheme which some sanitary solons in the Illinois Legislature have in mind is made effectual. It is proposed to establish an annual holiday when the houses, offices, factories, stores, theatres, and public buildings will be swept, dusted, scrubbed, and disinfected. This day will be called "Health Day," and for those who fail to observe it in a way satisfactory to the health authorities, there will be a penalty sufficiently severe to convince even the great unwashed of Chicago that soap and water are essential to health and hygiene.

A Hospital for the Chicago University.—It is reported that Mr. Rockefeller will build a therapeutic experiment institute on the grounds of the University of Chicago. It will include extensive laboratories and a large hospital. The main purpose of the institute will be the study of the cause and prevention of tuberculosis, cancer, and other diseases, together with a search after specific sera for the prevention and cure of infectious diseases.

New Medical Practice Law in Pennsylvania.—A bill has been introduced into the Pennslyvania Legislature providing that: "No person shall enter upon or continue in the practice of medicine or surgery in the State of Pennsylvania (or enter upon or continue in the profession or occupation of the treatment of patients or persons for disease or injury by the use of any medicine or by the use of any other means or agency whatsoever, either for a valuable consideration or without any charge or remuneration therefor), unless he or she shall have complied with the provisions of this act"—namely, that of May 18, 1893, relative to the examination and licensing of practitioners of medicine and surgery—"and shall have exhibited to the Prothonotary of the Court of Common Pleas of the county in which he or she desires to practise medicine or surgery (or to engage in the profession or occupation of the treatment of persons for disease or injury) a license duly granted to him or her as hereinbefore provided, whereupon he or she shall, upon the payment of one dollar, be duly registered in the office of the Prothonotary of the Court of Common Pleas in the said county; and any person violating any of the provisions of this act shall be guilty of a misdemeanor, and upon conviction thereof in the Court of Quarter Sessions of the county wherein the offense shall have been committed shall pay a fine not less than $200 nor more than $500 for each offense, and undergo an imprisonment of not less than thirty days nor more than six months in the county jail. Provided, however, that this act shall not apply to professional nurses in the prosecution of their profession."

Philadelphia County Medical Society.—At a stated meeting, held January 28, 1903, Dr. D. D. Smith read a paper entitled "Mouth-infection," in the course of which he pointed out the dangers, local and general, from failure to secure as nearly as practicable a condition of oral asepsis. For the accomplishment of this object periodic mechanical treatment of the mouth, and its contents, at intervals of about a month, was recommended, the surface of the teeth, and especially the interstices between the teeth, being rubbed with sticks of orangewood and fine pumice stone.

The State Care of Consumptives.—In a recently published interview, Dr. F. O. Donohue, chairman of the New York State Commission on Tuberculosis, expresses disapproval of the establishment of municipal and State hospitals for consumptives. He says that there are 50,000 sufferers from tuberculosis in New York State who would have to be provided for in case segregation were attempted. Further, he says that, in order to carry out any such plan, compulsory notification would be necessary, and the authorities would also have to be clothed with powers of compulsory removal and detention which, in the present state of public opinion and of our knowledge of the disease, would not be tolerated.

The Principles of Protection against Röntgen-light Dermatitis.—In the article with this title, by Dr. Carl Beck, published in the issue of January 31, the first two illustrations were inadvertently transposed, although the legends were correctly placed. The first photograph represents the cicatrization of the ulcer and should have been figure 2.

The Craig Colony Prize.—The prize of $200 annually given by Dr. Frederick Peterson for the best original essay on the etiology, pathology, and treatment of epilepsy, was awarded this year to Dr. Julius Donath of Budapest, Hungary, for his paper on "The Presence of Cholin in Epilepsy and Its Significance in the Production of the Convulsive Attack." Dr. Peterson again offers a prize of like amount for the same purpose and under the conditions: (1) That the paper must show original research work; (2) That the subject matter of the essay shall not have been before published; (3) That all manuscripts submitted shall be in English and shall be sent to Dr. Peterson at 4 West Fiftieth Street, New York City, before September 30, 1903, the successful manuscript becoming the exclusive property of the Craig Colony.

High Death Rate in Philadelphia.—For the week ended January 31 there were reported to the Philadelphia Board of Health 623 deaths, as compared with 615 for the preceding week and 530 for the corresponding week of last year. Pneumonia was responsible for 113 of the deaths, pulmonary tuberculosis for 65, diseases of the heart for 55, old age for 34, and typhoid fever for 30. Of the last-named disease 325 cases were reported, as compared with 294 for the preceding week. It was estimated that 4,000 cases were under treatment. For the entire month there were reported 1,303 cases of typhoid fever, with 161 deaths.

Crimes of Passion in France.—Out of nearly two hundred murders committed in France in 1900, over 75 per cent. had sexual passion as their exciting cause. In a still larger number of assaults and

attempted murders, this motive existed in a similar proportion. French juries almost always recommend to mercy these sexual criminals.

The Late Dr. F. E. Martindale.—At a recent meeting of the Richmond County (N. Y.) Medical Society, the following resolutions were passed:

Whereas, It has pleased the Lord to remove from our midst our fellow member, Dr. Frank E. Martindale;

Resolved, That we, his associates of the Richmond County Medical Society, of which he has been a prominent member for thirty-three years, vice-president for two years and president for four years, in meeting assembled, hereby record our profound sorrow at the loss of our fellow member;

Resolved, That the sympathy of this society be and hereby is extended to the family of the deceased in their sad bereavement;

Resolved, That the secretary be instructed to forward a copy of these resolutions suitably engrossed to the family of the deceased, and that he shall publish a copy of them in the local and medical papers.

Jefferson Scales, M.D.,
Horace W. Patterson, M.D., } Committee.

Obituary Notes.—Dr. Morrill Wyman of Cambridge, Mass., died on January 30, at the age of ninety years. He was graduated in Arts from Harvard University in 1833, and in medicine from the medical department of the same university in 1837. He practised his profession continuously for over sixty years. In 1853 he was appointed Adjunct Professor of the Theory and Practice of Medicine at Harvard, but retained the chair only three years. He had been an overseer of Harvard since 1875 and received the degree of Doctor of Laws from the university in 1885. He was an active member of the Massachusetts Medical Society for many years.

Dr. Harrison Augustus Lemen of Denver died on January 21 of chronic nephritis. He was born at Ridge Prairie, Ill., in 1840, and was graduated from the St. Louis Medical College in the class of 1864. He removed to Denver in 1874 and was placed in charge of the County Hospital, a position which he retained for five years. He was for many years a member of the Colorado State Board of Health. He was elected president of the Denver Medical Association, and served in the State Medical Society in the same capacity for the years 1882–1883. He was a charter member of the faculty of the medical department of the University of Denver, and at the time of his death was Emeritus Professor of the Principles and Practice of Medicine in that institution. He retired from active practice in 1893 on account of declining health. He had two brothers in the medical profession. Drs. L. E. Lemen of Denver, and E. C. Lemen of Upper Alton, Ill.

Dr. Henry Addison Mandeville of South Orange died. He was born in Newburgh, N. Y., on December 17, 1858. He entered New York University at the age of thirteen years, and was the youngest student ever matriculated at the university. After graduation he entered the college of Physicians and Surgeons, receiving his medical degree in 1881. He associated himself with Dr. Thomas H. Burchard and built up a large practice, but removed to South Orange, fifteen years ago. He remained as attending surgeon to the Colored Hospital in New York until recently. He was a director of the riding and driving club of the Oranges, a member of the Essex County Country Club, the Orange Club, the New York Pathological Society, the New York Academy of Medicine, Hospital Graduates' Club, Manhattan Surgical Society, Psi Upsilon Club, New York Athletic Club, and Downtown Insurance Club.

Dr. James M. Ridge died on January 30 at his home in Camden, N. J. He was seventy-six years of age, and was born in Bucks County, Pa. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1852, and was connected with the State Board of Health for several years.

Dr. Lucian H. Shepherd of Oswego, N. Y., died on January 25, of typhoid fever, at the age of thirty-seven years. He was a graduate of the Medical Department of the University of Syracuse in the class of 1895, and was a member of the Oswego County Medical Society.

Dr. John Morris, aged seventy-nine years, formerly postmaster of Baltimore, and for thirty years President of the School Board in that city, died there on January 29 from the infirmities of old age. In 1855 Dr. Morris was presented with a gold medal by the citizens of Norfolk, Va., for his volunteer services in combating the yellow fever.

Dr. John C. Hackett of Millington, Md., died on January 23, at the age of forty-six years. He was a graduate of Jefferson Medical College, Philadelphia, in the class of 1883.

New Instruments.

AN EMERGENCY MILK WARMER FOR INFANTS AND YOUNG CHILDREN.*

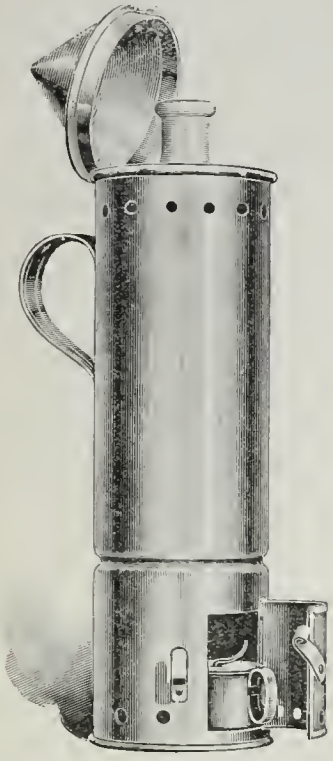
By JACOB SOBEL, M.D.,
NEW YORK.
ATTENDING PHYSICIAN TO THE DEPARTMENT OF CHILDREN'S DISEASES AT THE BETH ISRAEL HOSPITAL DISPENSARY.

It is conceded that a proper temperature of milk in the bottle feeding of infants and young children is one of the most important requisites for the prevention of digestive disturbances. Milk that is ingested habitually when cold, or much below the temperature designed by nature, is not only apt to chill the gastric mucosa, and thereby retard the process of digestion, but it may increase peristalsis, cause colic, and produce irregular stools, with all their attendant consequences. It is furthermore granted that the cooler the milk is kept (45°-50°F.) from milking time until its consumption, the less will be the liability of fermentative and other changes.

The method generally in vogue for warming milk, be it raw, pasteurized, or sterilized, has been to place the bottle in a receiver containing cold water, and then to raise the temperature of the latter to or about the boiling point, by means of gas or lamplight; or to heat the water first, and then to place the bottle of milk in it. Under ordinary circumstances, such simple measures prove eminently satisfactory. There are occasions, however, on which the mother is desirous of taking the child to the seashore for the day, on the floating hospital ships or recreation piers, to the city parks, or to similar places; she may, in fact, be directed by the attending physician to keep the child in the open air as much as possible. How can she procure warm milk under such conditions? To obviate this difficulty, that is to keep the heated milk warm, various devices have been recommended, and different warmers have been placed on sale. Wrapping the heated bottles in shawls, blankets, woolen covers, etc., has been resorted to by mothers; copper and other compartments, surrounded by felt or asbestos covers, have been advocated, all with the aim of keeping the milk at a desirable temperature.

*Presented at a meeting of the Harlem Medical Association, November 5, 1902.

It is true that these measures keep milk, which was originally raised to a high temperature (160°-212° F.) at about 98° to 100° F., for a comparatively short time outdoors, as I have been able to verify by numerous experiments; so that *at best* the mother can remain away merely from one feeding to the other. I have been informed of this fact by many mothers, some having gone so far as to say that they did not take their babies for a day's outing, on account of their inability to warm the milk properly, or to keep it at a desirable temperature. For these



reasons I have been led to improvise a milk warmer, which may be carried about and used advantageously both in and outdoors.

The apparatus is constructed mainly of tin, and is divided into two compartments. The upper one has a double jacket; the inner, with its copper base, serves as a receptacle for the bottle, while the outer is separated from the inner through its entire course, by an interval of three-sixteenths of an inch, which enables the heat to envelop the inner jacket more completely, and thus heat the water more rapidly. The outer jacket has eleven perforations at the top for the escape of impure air, and the maintenance of a current from below upward. The upper compartment is so constructed as to hold an eight-ounce cylindrical bottle, and is surmounted by a conical-shaped cover, provided with a hinge-joint and a snap-catch. A curved handle is riveted firmly to the outer jacket. The lower compartment acts as a receiver for the alcohol lamp; the latter is made of tin, contains absorbent cotton, has a handle which facilitates its removal from or its replacement into the groove at the sides of the base on which it rests, and a cover for extinguishing the flame. This cover has a curved handle, which may be used for withdrawing the lamp, in case it becomes hot. A small door with hinges, a catch and twelve surrounding perforations, through which the air to feed the flame passes, complete the apparatus. The warmer is 11½ inches in height, 3 inches at its widest part, and weighs one pound. The method of use is as follows: An eight-ounce bottle, containing the required quantity of milk, with a stopper of non-absorbent cotton or cork, is put into the upper compartment, water is added to the level of the inner jacket or of the milk, and the lid is fastened; the lamp, to which a small quantity of wood alcohol is added, or which has been saturated previously, is then ignited, and the lower door is shut gradually. In three to four minutes, the water is heated sufficiently to raise the temperature of the milk to the desirable degree, which I have found from experience to be 102° to 105° F., the lower door is then opened, the lamp removed, the flame smothered by the lamp's covering, the top cover reflected, the bottle taken out and well shaken. After the nipple has been attached, the warmth of the milk should be tested, by allowing a few drops to fall upon the front of the wrist.

It is common knowledge that an alcohol flame can be extinguished only by vigorous blowing; advantage was taken of this fact in its application for outdoor use. Under ordinary atmospheric conditions, even with moderate draughts, the lamp will burn; in exceptional instances, with high winds, it may be necessary to ignite the alcohol a second time. For home use the lower door need not be shut.

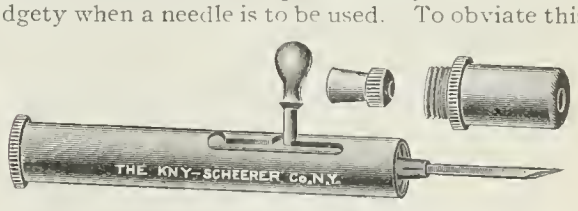
In the summer it is inadvisable to heat three or four bottles before leaving, in the hope that they will be warm enough at feeding time; on the contrary, during these months, the cooler the milk is kept, previous to heating, the less will be the danger of contamination. With this apparatus milk may be heated only as the occasion arises. It can hardly be suggested that the nutritive qualities of the milk are endangered by this method, since the heat is not prolonged for any length of time; nor can the objection be raised that "the baby will become restless by having to wait for its food after waking," when we consider that the whole affair takes but a few minutes. The apparatus is portable and light in weight, the bottle is held in place, the alcohol lamp is immovable, and the price is cheap. It is presented as an emergency milk warmer for infants and young children, though we are mindful of the fact that other applications may suggest themselves. The warmer is manufactured by the Hospital Supply Company.

1828 Madison Avenue.

A BLOOD LANCE.

By H. J. BOLDT, M.D.,
NEW YORK.

The desirability of making blood examinations of patients, whether they be in the care of general practitioners or of specialists, is recognized. While it is immaterial with what the skin is pricked, so long as the wanted blood is procured, and so long as the little contrivance is previously made aseptic, it does sometimes occur that a patient may be somewhat fidgety when a needle is to be used. To obviate this,



Dr. L. H. Warner has had a needle made which is enclosed in a metallic case and controlled by a spring, so that it cannot be seen by the patient. The needle, however, is stationary, so that it cannot be changed. To overcome this, I have had the Kny-Scheerer Company make one for me in which the Hagedorn needle, which is to be used in the holder, is interchangeable, so that a new needle may be inserted whenever one wishes to do so. The advantage of this needle is so obvious, in my opinion, that I have thought it desirable to call attention to it.

39 East Sixty-first Street.

Progress of Medical Science.

The Boston Medical and Surgical Journal, January 29, 1903.

A Report of Eleven Cases of Morbus Coxæ Senilis.—W. E. Blodgett says that of these eleven cases six are men. There is a family history of joint disease in five of the cases. In six there is a history of trauma, which was apparently a factor in determining the onset of the disease. In five no etiology was discovered. The general treatment has been forced feeding, mild catharsis, and the copious ingestion of water; elixir of the triple phosphates has been the medication commonly used, if any. Local treatment has been protection, immobilization, and, in picked cases of anchylosis, or very deficient mobility, excision. One case in which anchylosis greatly disabled the patient was excised several months ago; the symptoms, which had been extraordinarily acute, were immediately relieved, and the patient is now freely walking with crutches and convalescent hip splint. Of eight cases treated by partial immobilization and protection during the day, six have already improved, and one has nearly recovered, thus emphasizing the benefit of this form of treatment in this troublesome and sometimes neglected class of cases.

Chylous Ascites; Report of a Case Due to Total Occlusion of the Thoracic Duct.—Perley P. Comey and Wm. W. McKibben (pathologist) report a case and give the following résumé of their studies in relation to the subject. Knowing that acute and chronic inflammations of the lymphatic vessels are rarely a primary disease, but always result from inflammation of the surrounding tissues, or parts drained by the affected vessels, some cause outside of the thoracic duct must be found to explain the case at hand. This cause is attributed to an old tuberculous focus at the left apex, where a half dozen nodules were found which had undergone caseous and calcareous degeneration, and were surrounded by thick fibrous walls. This fibrous tissue had so developed in the surrounding pulmonary tissue that no sembance of alveoli were to be found. The process had not stopped here, but the two lobes, compressed so that together they were no larger than the two fists, were so tightly bound down to the upper and posterior pleural wall by firm fibrous adhesions that the lung could not be torn out, but had to be cut, this producing a loud grating noise. The thoracic dust winds directly around the left apex as it comes from behind the œsophagus at the seventh cervical vertebra, and comes outward to empty into the left subclavian vein. What an enormous process this fibroid degeneration was can be recognized by the sections taken at a dozen different levels, where it is seen that the densest fibroid deposit is in the lumen of the dust as well as in the walls themselves, where occasionally, when a few muscular fibers are left, the fibrous tissue is seen deposited between these fibers.

Journal of the American Medical Association, Jan. 24, 1903.

Typhoid Fever in an Infant Under One Year of Age.—The case is reported by E. F. Brush, who reviews the literature bearing on this particular age limitaton of typhoid fever. His own patient was a baby living under very unfavorable hygienic surroundings. The mother was taken down with the fever when the baby was six months old, and two months later the baby itself was attacked. When seen by the author, it had been sick about ten days. The case was seen during the author's vacation in the Maine woods and, as far as is known, recovered.

The Salicylates in Acute Rheumatism.—J. J. Walsh believes that in order to derive real benefit from the use of the salicylates in rheumatism we must employ a daily dosage of from 90 to 120 grains during the acute stage of the disease. Nervous and digestive disturbances are contraindications to their use, as is also impairment of renal integrity. There is such a thing as salicylic dyspnœa characterized by rapid though deep breathing. If persistent, some other remedy must be employed. The acid derived from the genuine oil of wintergreen is better borne than are the synthetic products. The daily dosage should be so arranged that none of the remedy need be taken after four in the afternoon until the next morning. With a view to the prevention of heart complications, alkalies should always be combined with the salicylates. If the latter do no good by the third day, they should be discontinued in favor of phenacetin or antipyrin. There is considerable doubt as to whether the salicylates really affect the rheumatic process itself, though they do markedly relieve the usual pain, fever, and restlessness.

Journal of the American Medical Association, Jan. 31, 1903.

The Teeth as a Cause of Pathological Conditions in the Throat, Nose, and Ear.—Illustrative cases are given by K. W. Baldwin. These include sinus disease, tonsillitis, peritonsillitis, and permanent aural damage following acute otitis media. The paper is, in the main, a plea for the association of dentistry with rhinology, otology, and laryngology in clinical work.

Some Unappreciated Causes of Anæmia in Childhood.—W. C. Hollopeter calls attention to the fact that in children the mouth is frequently unhygienic, giving rise to gastrointestinal troubles; remote infectious diseases are common, including all troubles due to pyogenic organisms, as osteomyelitis, ulcerative endocarditis, empyema, suppurative meningitis, suppurative nephritis, not to exclude the more obscure septic conditions characterized by irregular fever, purpura, bleeding gums, and various toxic conditions. Again, we must recognize the fact that there must be a limit to the power of the stomach to cope with a constant stream of pus pouring into it from the decaying teeth. The acid of the gastric juice may destroy the toxic influence for a time, but it is eventually overwhelmed, and ill health the result. Again, asepsis of the mouth of the child (adult also) is as much to the physician as is asepsis to the surgeon—a necessity to life and health.

Spontaneous Hemorrhages in New-born Children.—Thirteen cases are reported by I. A. Abt, who discusses the etiology of the affection. In his view a certain number of cases are due to sepsis, but the latter may arise from a wide variety of causes. In his own cases the sites of bleeding were as follows: Umbilicus three times under the skin, six; nose, four; mouth, seven; stomach, two; vagina, two; bowel, five; ear, one. General experience as to treatment leads him to lay down the following propositions: (1) Internal remedies, as ergot, tincture of chloride of iron and extract of suprarenal gland have absolutely no influence on the progress of the disease. (2) The local treatment of the disease by styptics of whatever kind, packing with gauze (as when the hemorrhage occurs from the vagina), and even the local application of suprarenal gland extract, are without permanent influence on the intensity or duration of the hemorrhage. He refers to the use of gelatin in this condition, stating that a pad of sterile gauze or a compress may be soaked in a ten-per-cent. gelatin in normal salt solution and applied to the bleeding area. A small amount of bichloride of mercury may be added to this solution. Its preparation must include careful sterilization. A two-per-cent. gelatin in normal salt solution may be given subcutaneously. This should be sterilized repeatedly—that is, for three successive days. The peptone which is ordinarily added to gelatin for culture material should be omitted, as it counteracts the coagulating effect of the gelatin. From 25 to 50 c.c. of this solution may be given subcutaneously to a new-born infant, and may be repeated once daily. Later experience, derived from experiments on rabbits and observation of children, has led the author to utter a caution regarding the subcutaneous use of gelatin, for it has been found that even sterilized gelatin contains toxic products, probably ptomains, but its local use and use by the mouth are warmly recommended. No contraindication exists against this method of employment.

Medical News, January 31, 1903.

Is Any Diseased Condition Necessarily Self-limited?—Edwin R. Maxson is thoroughly convinced that typhoid fever and all contagious diseases have not necessarily self-limitation. His treatment of typhoid fever is as follows: He begins with an antiseptic, generally sulphocarbolate of sodium, from two to four grains in solution for adults, with two or three drops of tincture of nux vomica. This is given every six hours, at 6 and 12 o'clock, alternating with two or three grains of cinchonidine, at 9 and 3. An improved cathartic pill is given daily, with a warm foot-bath at evening and sinapisms over the abdomen morning and night. For food, hot toast-water, half milk, as a drink, or hot bread and milk at meal time, is given, if tolerated. The patient is kept out of bed during the day, as far as is safe, in order to secure better rest at night. The results of this treatment have seemed to show an arrest of the disease, when the cases were seen early—indeed, an abortion of the disease seems to have taken place. In cases seen a little later, when the microbial or other cause had poisoned the system more generally, and especially when it had involved the intestinal glands so that there was congestion and incipient inflammation, warm sinapisms all over the abdomen were used twice a day, as well as the warm foot-baths, and the disease usually developed no complications. The patients were generally out of bed in the daytime, and were able to get about light business in about a week. In a later stage when incipient ulceration of the intestines threatened, and perhaps cerebromeningeal inflammation, there was additional treatment with wet cups to the back of the neck, and very rarely a blister to the epigastrium was used. On the average, these patients have been out in about two weeks. Thus,

with the use of antiseptics, the average duration of the disease is ten or eleven days, while before the use of antiseptics it was about twenty-one days. Besides this, one-third of the cases treated in the earliest stages were aborted. The writer's observations in the treatment of strictly contagious diseases correspond very nearly with those just described. Success will largely depend upon the *stage* of the disease in which treatment is begun. He believes that there is not necessarily self-limitation in any diseased condition. All habits deleterious to life and health should be avoided, and all efforts for aborting, cutting short, and rendering lighter all diseases should be made.

New York Medical Journal, January 24, 1903.

Rectal Fistula Curable without Operation.—A. Rose details the particulars of a case of anal fistula treated by the passage of carbonic-acid gas through the fistulous tract. His patient was a man of thirty years who had been complaining for six months. Daily passages of the gas were made, and in fifteen days the sinus had entirely closed.

The Treatment of Acute Septicæmia by the Intravenous Infusion of a Solution of Formic Aldehyde, with Report of a Case.—The patient of C. C. Barrows was a negress aged twenty-six years, and in labor at the time of admission to hospital. Next day she was delivered of a six months' macerated fœtus. Septic infection had already commenced before delivery and became more pronounced soon after. She received the usual antiseptic douches and was curetted, but with only temporary relief to the septic symptoms. Examination of the blood showed the plasmodia of malaria and a leucocytosis of 18,000; also pure cultures of streptococcus. She was at once given an intravenous infusion of 500 c.c. of a 1 to 5,000 aqueous solution of formalin. In three hours her temperature had fallen to 105°, and in six hours it had fallen to 101°, her pulse being 104 and her respiration 28. For three hours the temperature remained at 101°, when it gradually began to rise until it reached 103°, her pulse having risen to 120. It remained at 103° for three hours, when it plunged downward, until, in three hours, the thermometer registered, by the rectum, only 95°. The pulse had then fallen to 86 and the respiration to 22. In twelve hours the temperature had reached 102°, and the pulse 110. It then dropped to normal, but rapidly rose to 103°, although the pulse did not go higher than 112. Although a second blood culture had been taken, there had not been time for a report, so it was decided to give her a second infusion, 750 c.c. of the same solution being then given her. There was a slight chill without a further rise of temperature, which in the course of twelve hours fell to normal. At the time the case was reported the patient was up and about, and apparently well. Cultures made subsequent to the first formalin injection were all free from streptococci. Barrows believes that in such cases the formalin should be dissolved in a normal salt solution.

American Medicine, January 31, 1903.

The Control of Mouth-breathing at Night.—Stewart W. Tufts believes that the most simple method for preventing mouth-breathing that can be devised is to stick a piece of silk isinglass court-plaster, about ⅜ by 1¼ inches, across the closed lips. It can be very quickly removed and does not irritate the lips. The writer finds that at least 90 per cent. of his patients with acute and chronic diseases of the respiratory tract are mouth-breathers at night. This is the result of very careful observation. A nose to be normal must be used constantly. If it is not so used, the mucous membrane congests and gradually thickens from hypernutrition. Air inspired through the nose receives from 20° to 40° of heat, and becomes at least two-thirds saturated with moisture, and thus the nose becomes a most effective germ filter. The mouth has none of these functions, and when it is used for breathing the lungs must receive many germs and suffer injury from the unmodified air. When the immense mortality from lung diseasesis considered, the importance of this subject can better be realized. The writer finds his general results better in the treatment of respiratory diseases since the use of this method.

A Note on the Anatomy of the Perirenal Fatty Tissues.—W. W. Keen speaks of the anatomical disposition of the perirenal fat which he does not find described in the text-books, the recognition of which greatly facilitates the finding of the kidney. There are two distinct layers of fatty tissue surrounding the kidney itself: First, that which should be called the transversalis layer of fat, and, secondly, the proper perinephric fat or fatty envelope surrounding the kidney itself. As soon as the fat bulges through the incision, in operations on the kidney, if it is carefully cut or torn through, gradually deepening the incision or tear, a distinct interval between these two layers will be found, which is recognized by a layer of connective tissue, similar to that which is found, for example, between the internal oblique and transversalis muscles. Then comes the second layer of fat. If this be incised or torn through and drawn into the wound, the opening thus made in it becomes a sort of infundibulum or funnel-shaped opening, at the bottom of which the kidney is invariably found. Occasionally the first layer of fat does not extend so far posteriorly as the second layer, but commonly, so far as the operating surgeon is concerned, they lie superposed. After giving this description the writer then presents another by one of his assistants, who, at his request, has made two dissections of the parts.

Tea and Coffee Intoxication.—Emil King gives the physiologic action of caffein and thein as follows: (1) They cause wakefulness, greater capacity for mental labor, and increased activity of thought by stimulation of the brain cells. Increase of the reflexes through stimulation of the spinal cord. (2) The heart's action is strengthened, being first slowed, and then becoming more rapid and irregular. This effect is likened to that of digitalis, but is more evanescent and also more rapid. It is generally conceded that this effect is due to stimulation of the medulla and not to direct action on the heart. (3) Diuresis occurs by direct stimulation of the secretory epithelium of the kidney, the solid as well as the liquid constituents of the urine being increased. (4) Thein is said, by some authorities, to have the following action in addition to the above: It causes a fall in body temperature, while caffein causes a rise; its action is more marked on the sensory system, and caffein on the motor system; it is a powerful local anæsthetic and analgesic, while caffeine has no such effect. (5) The tannic acid exerts its well-known astringent properties on the alimentary canal, and undoubtedly has an injurious effect on gastric and intestinal digestion through the formation of insoluble compounds. Consequently, when used to excess, the following reactions may be expected: Exhaustion of the brain from constant overstimulation, insomnia, vertigo, headache, neuralgia, flashes of light, mental dulness with exhaustion of mind, disinclination to work, and melancholia; increased and irregular heart-action, ringing in the ears, muscular tremors; various forms of gastric and intestinal indigestion, with loss of appetite; diarrhœa when using coffee, and constipation with alternating attacks of diarrhœa when using tea; loss of bodily weight. In the treatment of these patients the essential point is to stop the habit.

Philadelphia Medical Journal, January 31, 1903.

The Relation of the Prefrontal Lobes to Mental Function.—Charles W. Burr reports a case in detail which he believes adds evidence in favor of the view that the prefrontal region is in closer relation with mental processes than some other parts of the brain. This is not saying that the prefrontal region is the center of mind. It is not yet decided whether the left or the right lobe is of predominant importance. Disease in either may cause mental symptoms. The area of the cerebral cortex that can be excluded with a fair degree of certainty from all or nearly all mental processes is not very large. It includes the motor centers on either side of the fissure of Rolando, the center of half vision in the cuneus, the so-called motor speech center in Broca's convolution, and the center of common sensation which is not yet accurately fixed. The writer believes that disease strictly confined to one of these areas never causes mental symptoms. The sensory speech centers have quite real relations to mental processes. There remain the great association areas of Flechsig, formerly called the silent regions, without motor or sensory functions, and with few or no projection fibers. The prefrontal region is one of them. Probably all of them combined form the organ of mind. Disease affecting any one of them may cause symptoms similar to those of prefrontal disease. In the cases of traumatic insanity, the lesions are always diffuse. If the prefrontal region were the center of mind, disease there alone should be common in insanity. But the fact is that when organic disease is present in insanity, it is always diffuse and involves the whole cortex—in fact, the entire hemisphere.

Tropical Dysentery.—Charles E. Kieffer defines dysentery as a symptom complex, depending upon an inflammation of the colon. The complex changes with the extent and location of the inflammatory process in the large bowel, and consists of numerous bowel movements containing blood, mucus, and intestinal structure, voided with intense pain and effort, tormina, and tenesmus, while there is severe abdominal tenderness and moderate febrile disturbance. When it is in full efflorescence, it is a disease of the tropics. Etiologically, it is divided into three main groups: Endemic or amœbic dysentery; epidemic, "specific," or bacillary dysen-

tery; and sporadic dysentery. Endemic dysentery is always present in the tropics. It is a colitis due to the amœba coli. Its onset is slow and insidious, its course severe, with a tendency to chronicity and relapses or recrudescences. It is also characterized by its liability to cause hepatitis. In this type serum reaction is absent. Death results from the sequelæ and complications. On the contrary, bacillary dysentery occurs in localized epidemics, smaller or larger, and it is not present as a constant *place* disease. Its course and onset are generally acute. Its chronicity is not so marked as that of the first type, and when chronic the symptoms are continuous. Amœbæ are absent. Serum reaction is present in dilution 1:40. The etiological factors of sporadic dysentery are distinct from those of the first two classes, and these cases embrace only about 5 per cent. of all cases of dysentery. These sporadic dysenteries may be due to chemical irritants, to mechanical irritants, or to various microorganisms, such as the bacillus pyocyaneus, the balantidium coli, and probably to the various micrococci of suppuration, especially the streptococcus pyogenes. The complications of acute dysentery are very similar to those of typhoid fever. The prognosis varies greatly with the conditions, the class of patients, and their resistance. As to treatment, the patient is first put to bed. The drugs of special value in this disease are ipecacuanha, and the salines. The preparations of bismuth are valuable adjutants. Other drugs are used, at times. For pain, the ice suppository, cold or heat to the abdomen, and opium are indicated. The diet should be absolute milk or liquid diet, and restricted in amount. A flannel abdominal band should be worn.

Berliner klinische Wochenschrift, January 12, 1903.

Lymphatic Structures of the Throat as Portals of Entry for Tuberculous Infection.—Sukehiko Ito has examined, microscopically, the various lymphatic structures in Waldeyer's so-called lymphatic throat ring, in order to ascertain the frequency of tuberculosis, especially primary tuberculosis, in the same. These structures were thus examined in 104 children. The diagnosis of tuberculosis was made upon the histological picture present, rather than upon the presence of tubercle bacilli. In none of the cases examined was a primary tuberculosis of these structures found. Secondary tuberculous lesions were found in five cases in the palatal tonsils, in two cases in the throat tonsils, in one case in the valleculæ epiglotticæ, and in one case in the mucous ganglia at the base of the tongue. In several of these cases the lesions were found simultaneously in two or more of these structures. Taking these into account, there were in all six cases in which secondary tuberculous lesions were present. It would, therefore, appear that primary tuberculosis of the lymphatic throat ring is of the greatest infrequency, and that even secondary tuberculosis is but rarely met with.

Berliner klinische Wochenschrift, January 15, 1903.

Immunity to Syphilis and Profeta's Law.—Von Düring thinks that there is no such thing as an hereditary immunity to syphilis, or a reduction in the power of the syphilitic virus when it is introduced into the offspring of syphilitics. Observations in Asia Minor, where syphilis is practically universal, have led the author to this view. There the children of syphilitics show secondary syphilitic lesions and symptoms of the same intensity as are observed elsewhere in the infected children of non-syphilitics. Profeta's law has been much misunderstood and misquoted. This observer never claimed that there was an hereditary immunity to syphilis, but only that the child of a syphilitic mother could be nursed by such a mother and not contract syphilis thereby. All those who have otherwise understood his law are in error concerning his actual meaning. It is certain that there is an *acquired* immunity to syphilis. Such an immunity is not, however, always absolute, as many cases of undoubted re-infection have definitely proved.

Operations Conducted without the Direct Use of the Finger.—König advises that all surgical operations be conducted without the direct use of the hands. This can be accomplished only by using instruments of a special design in which the handles are unusually long and of various appropriate shapes. The ability to conduct operations in this manner only comes with much experience, and expertness is only very gradually obtained. König's first attempts were made several years ago, and were at first confined entirely to operations upon the joints. Gradually the scope of the method has been enlarged until at the present time practically all varieties of operation are conducted by him in this manner. During the last year, out of 1,000 operations 600 were so conducted. Under this procedure the lesions heal much more rapidly, and suppuration never occurs. It has been amply demonstrated that a sterilization of the hands is impossible by any method now in use, and by the method here advocated the hand, as a source of infection, is completely excluded.

Antistreptococcus Serum in Scarlet Fever.—Paul Moser attacks Baginsky's recent article (*Berliner klinische Wochenschrift*, 1902, Nos. 48 and 49). With respect to the association of streptococci with scarlet fever, Baginsky has said neither more nor less than was previously known. This association was first demonstrated by Moser and Pirquet, and at the same time independently by Salge as the result of specific agglutination reactions. Furthermore, the agglutinating capabilities of streptococci were not first demonstrated by Aronson, as Baginsky claims, but by van de Velde and Paltauf. The first antistreptococcus serum which was produced came from Marmorek. Its therapeutic use, however, was unsatisfactory, and a second serum, produced along the same lines, was brought forward by Aronson. Baginsky's favorable opinion of Aronson's second serum was obtained after a trial of five weeks, a period entirely too short in which to judge the efficiency of any method of treatment. In the face of these facts, Baginsky's critical remarks with respect to my (Moser's) serum are entirely unwarranted; so much the more since Baginsky has had no experience whatsoever in its use. In any event it has been much more thoroughly tested than Aronson's later product, since it has been used in my clinic from November, 1900. During this time more than one hundred cases have been inoculated with the favorable results recently reported by me at Carlsbad. Any man who, from the results obtained with one serum, will endeavor to draw conclusions with respect to another, obtained by an entirely different method, is, to say the least, illogical.

Adolf Baginksy, in answer to the above, refers to an article which appeared in the *Berliner klinische Wochenschrift*, 1900, Nos. 27 and 28, and which was written conjointly by him and Sommerfeld. This was the first article which was written in which the close association of streptococci with scarlet fever was advanced upon scientific grounds. Baginsky admits that his recent use of Aronson's latter serum is insufficient for the deduction of positive conclusions. His criticism of the enthusiasm of Moser and others at Carlsbad was based upon general principles, as stated in the article referred to. Baginsky's experience has shown that very extensive use and great care are necessary before anything like positive conclusions can be drawn with respect to the efficiency of any serum in scarlet fever.

Hans Aronson, in referring to the above article of Moser's, says that he has specifically stated in all his (Aronson's) writings that his agglutination tests comprise the macroscopic instead of the microscopic reactions. All his claims to priority are based upon the results of such macroscopic tests. Aronson has frequently pointed out the many sources of error in any microscopic agglutination test in which streptococci are employed, and was the first to employ and recommend the macroscopic test as the most reliable. These distinctions have always been pointed out by Aronson in his writings, and it is hard to see how any one who has read the same could fall into Moser's erroneous understanding. Aronson's serum is not at all similar to Marmorek's, as may be easily demonstrated by testing their specific agglutinating power.

Deutsche medicinische Wochenschrift, January 8, 1903.

Sclerodermatitis in Childhood.—Wilhelm Ebstein reports a case. The history showed an attack of rheumatism which immediately preceded the cutaneous affection, but when the patient came under observation no signs of rheumatism were present. The cutaneous lesions were well generalized over the surface of the body, but no atrophy or shrinking of the skin was anywhere present. The treatment was antirheumatic and included massage and the internal administration of sodium salicylate. Prompt recovery took place. For this reason the author is inclined to think that etiological relations existed between the dermatitis and the rheumatism. However, this is by no means certain. This form of dermatitis is, as a rule, very resistant to treatment. This is especially the case after cutaneous atrophy or contraction has taken place. Hence the results of the treatment in this case are very suggestive that in some cases at least sclerodermatitis is rheumatic in origin.

Syphilitic Heart Affections.—J. W. Runeberg says that the most important of these is a sclerogummatous arteritis of the coronary arteries. The clinical picture closely corresponds to that of true angina pectoris. It is to be differentiated from pseudoangina pectoris by the presence of the irregular pulse and muffled heart sounds which are never present in the latter. More difficult is the differentiation of syphilitic from ordinary sclerosis of the coronary arteries. The syphilitic form, as a rule, develops before middle life and is limited to the coronary arteries, while the reverse holds true for the ordinary form. The author thinks that coronary arteritis which develops before middle life in eight or nine cases out of ten is of

syphilitic origin. Next in importance in syphilitic cardiac affections comes sclerogummatous arteritis. This is sooner or later complicated by insufficiency of the aortic valves and aortic aneurysm. Here also the age of the patient is of great aid in the diagnosis. Many cases under middle life are of syphilitic origin. Diffuse gummatous myocarditis of the heart is somewhat rare, but more frequent than circumscribed cardiac gummata, which are very frequent. Gummatous endocarditis and pericarditis are also very infrequent. It is doubtful whether a primary gummatous endocarditis has ever been oberved. The various forms of cardiac syphilis are only found in the acquired form of this disease and in an advanced stage of the same. Their accurate diagnosis is of the greatest practical importance, since by appropriate antisyphilitic treatment they may be greatly improved, and in some cases absolutely cured, if such treatment is begun before they are too far advanced.

Münchener medicinische Wochenschrift, January 13, 1903.

The Union of Hæmolytic Amboceptors with the Red Blood Cells.—It has been generally thought that the hæmolytic amboceptors are firmly united to the red blood cells. J. Morgenroth, by a series of experiments, shows that this union is not as firm as has been supposed, since such amboceptors can be separated in certain amount from erythrocytes, to which they are united by repeated washing in saline solution. If, however, the red blood cells contain both amboceptor and complement the amboceptor cannot be separated therefrom.

French and Italian Journals.

Fatty Inguinal Hernias.—Henri Caubet states that these fatty hernias of the inguinal region consist of a tumor which occupies the inguinal canal and which is seen as soon as the aponeurosis of the external oblique is incised. This fatty tumor encloses the hernial sac. The adipose mass is lobulated and slightly vascular. It is sometimes surrounded by a thin cellular fascia, which separates it from the other parts in the inguinal canal. It is a hernial lipoma. It is generally elongated in form; its volume varies, most often, however, being about the size of a walnut or almond It is always easy to isolate, and presents no adhesions to the parts of the spermatic cord. The radical cure does not differ from that of the common inguinal hernia.—*La Presse Médicale*, January 10, 1903.

Physiological and Clinical Study of Animal Heat: Measures of the Intensity of Organic Combustions by Thermometry.—J. Tétan proposes the following principles: The rapidity of ascension of the mercurial column is in direct proportion to the activity of the diathermanous power of the skin; that is, to the rapidity with which the body yields the heat which it produces. This rapidity is variable for the same person, according to the different parts of the body, and the different hours of the day and night, but within narrow limits. This rapidity is independent of the temperature of the body, or at least it is not in proportion to this temperature. The ascending rapidity is proportional to the surface of contact of the instrument on the skin.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, January 4, 1903.

Changes in the Spleen in Cirrhosis of the Liver.—F. Azzurrini concludes from his researches that in the splenomagaly following ordinary hepatic cirrhosis, the histological changes found in the spleen are identical with those found in the spleen from stasis, and consist: (1) In a dilatation of the veins and of the cavernous tissue of the splenic pulp due to an accumulation of red blood cells. (2) In a successive dilatation of the capillaries of the Malpighian follicles proceeding from the periphery to the central artery, with exudation of the blood cells, and disintegration of the cellular elements composing the follicles. (3) Inspissation of the capsule, trabeculæ, and adventitia of the veins. (4) In an abnormal destruction of red blood cells. (5) In a series of degenerative processes which attack the cells of the splenic pulp itself, and which end in their granular disintegration.—*Lo Sperimentale*, No. V-VI, 1902.

The Pathogenesis of Progressive Pernicious Anæmia.—Giuseppe Finzi concludes that a factor in the production of pernicious anæmia is any extensive alteration in the mesenteric glands, which assist in the process of chylification, and hence to the renewal of the elements of the blood. While it is comprehensible that intestinal atrophy may be considered secondary to anæmia, it is not easy to see why enlargement of the mesenteric glands should be supposed to be secondary to alterations in the blood. It should rather be held as the result of some infection originating in the intestinal mucosa, whether as a complication of chronic catarrh, parasites, tuberculosis, or cancer. And while, on the one hand, pernicious anæmia may follow a slow puerperal infective process with lesions of the hematopoietic organs, on the other hand, it is probable that in not a few cases its source of infection is to be found in the lymphatic-mesenteric apparatus, since the mesenteric follicles and glands are to be regarded as the principal seat of the formation and the transformation of the morphological elements of the lymph.—*La Riforma Medica*, December 27 and 29, 1902.

Diffuse Tuberculosis of the Pelvic Cellular Tissue with Chalky Nodules.—A. Croisier reports this case of a man, fifty years old, who first noticed at the level of the ischial tuberosity on the right side the appearance of a painless swelling that gradually increased in size. When it reached the size of a fist it was incised. A yellow liquid was evacuated, with a considerable quantity of whitish concretions. A large phlegmon with fever and abundant suppuration developed. The acute symptoms subsided, but the suppuration continued. The pus was very fluid, and resembled that of a cold abscess. There were various fistulas present. The writer first saw the patient at this stage. There was an advanced state of cachexia. The patient was operated upon, and the various fistulas were connected by one incision. There were abundant fungosities, and concretions as large as a small pea or a nut, very hard, whitish yellow, and mulberry in form. Anatomical examination of the fungosities showed clearly their tuberculous nature; while chemical examination of the concretions determined them to be made up of phosphate of lime, carbonate of lime, and phosphate of magnesia.—*La Médecine Moderne*, January 7, 1903.

Electricity in the Treatment of Metatarsalgia.—F. Piccinino says that it is a mistake to incriminate tight shoes alone as the cause of this painful affection, as it is frequently found in neurasthenic or gouty individuals, after much walking, bicycling, or riding. In some cases synovitis of the fourth metatarsal bone, tuberculous osteitis, and even a new bony growth have been found. Quite recently the author had occasion to treat a patient who for seven years had suffered from acute pain in the metatarsal region of the right foot; in the beginning it was intermittent and bearable, but it had of late become continuous and extremely painful. Having decided to try the effect of galvanism, the author applied it in the following way: a large square electrode covered with chamois skin was placed on the lower third of the right thigh, anteriorly, while the positive electrode was introduced into a wooden tub filled with tepid water, into which the patient's foot was introduced. A current of 15 ma. was turned on and allowed to flow for ten minutes. On the following day the strength was increased to 20 ma. and the time to fifteen minutes. There was improvement from the start, and after the fifth application the pain ceased altogether at night, and in the daytime was less severe and appeared only after walking. A half cubic centimeter of a 2-percent. solution of cocaine was injected for two days, the electrical treatment being continued. Two months have elapsed since the treatment, and as yet the patient has had no pain in the foot, which so tormented her for seven years.—*Annali di Elettricità Medica e Terapia Fisica*, December, 1902.

Two Cases of Neurosis of the Pylorus.—L. Pinatelle has assisted at two operations for neuropathic affections of the stomach. The first patient was a woman thirty-two years old. Both family and personal history were excellent. For two years she had had gastric trouble. At first this consisted merely of a vague malaise coming on a half hour after eating. This uncomfortable sensation was localized in the epigastric region, radiating sometimes to the dorsal region. Although it was not influenced by position, it was increased by rich food. There had never been hæmatemesis nor vomiting, but there were frequent acid regurgitations and persistent constipation. In the last year the pain increased, and the disturbance was always of the hyperchlorhydric type. On entrance to the hospital, a small, painless tumor was clearly felt in the region of the pylorus. It was round and hard, and relatively mobile, and gave the impression of being a neoplasm of the pylorus. The test breakfast was rapidly absorbed. On emptying the stomach in less than a half hour after the ingestion of this food, the liquid was found to contain no lactic acid, but a strong proportion of hydrochloric acid. Laparotomy was performed, and the phantom tumor entirely disappeared. The pylorus was reduced in volume and thickened. It was hard but freely movable. But after half a minute of examination, the pylorus gradually changed, becoming normal at that point, while a little further up, on the anterior surface of the pyloric vestibule, appeared a new knot of contraction. After a simple stretching of the pylorus, the abdomen was closed. Ten days later the patient left the hospital and declared that she had not suffered at all since the operation. The second case was one of severe nervous vomiting. This was caused by antiperistalsis of the stomach, which caused this organ to assume the form of the intestine of a dog. There was a certain regularity or rhythm about these muscular contractions. The affection was rebellious to all treatment. Gastroenterostomy

was proposed, but the patient objected, and died from inanition.—*Gazette des Hôpitaux Civils et Militaires*, January 8, 1903.

American Journal of the Medical Sciences, December, 1902.

Tuberculosis of the Parotid Gland; Excision of the Tumor; Recovery.—Charles L. Scudder relates the history of this case. The patient was a woman, aged fifty-seven years, mother of three children. Her health has always been good. Five years ago a small swelling appeared just below the lobule of her right ear. It grew slowly for three years. For over a year it grew painlessly but perceptibly. There were no subjective symptoms. Her hearing was good. There were no pressure disturbances. The swelling was slightly movable upon the parts beneath. It was not attached to the skin, and was not tender on palpation. The chest was negative. The tumor was removed by operation. She left the hospital one week after operation. A year and a half later there was no recurrence. Microscopical examination showed parotid gland structure with many small foci composed of epithelioid, small, round, and numesous giant cells, with cheesy degenerations: tuberculosis.

Autopsy in a Case of Adiposis Dolorosa.—F. X. Dercum and D. J. McCarthy report this case of a man, thirty-nine years old. It is the fifth instance of a patient with this disease coming to autopsy. In this case changes in the thyroid are very slight. The changes in the pituitary body are those of enlargement with new formation. An interstitial neuritis is present. The presence of hæmolymph glands probably indicates that there is a profound disturbance of nutrition, due, perhaps, to disease of the thyroid and pituitary glands. They probably indicate efforts at compensation and have a compensatory function. The writers believe that this is the first instance in which hæmolymph glands have ever been found in man as new-formed structures. They add, in regard to the changes in the pituitary body, that they are very significant. The pituitary body is thus brought into relation, though, perhaps, indirectly, with a fat-producing or fat-destroying function—a relation which has not been considered up to this time. In every one of the five cases which have come to autopsy, the thyroid gland has been diseased. Both the clinical findings and the results of the autopsies make it sure that adiposis dolorosa is a well-defined clinical entity.

The Surgical Treatment of Cirrhosis of the Liver.—Robert B. Greenough concludes: (1) The condition known as biliary cirrhosis, with enlarged liver, jaundice, and fever and without ascites, is accompanied in a certain proportion of cases by an infection of the bile-ducts. The drainage of the bile-ducts by cholecystostomy is a proper operation for the relief of this condition. When evidence of infection is present and symptomatic treatment has failed to effect relief. (2) Of 105 cases of liver cirrhosis which presented the symptoms of ascites, 42 per cent. were improved and 58 per cent. not improved by Talma's operation or one of its modifications. The mortality within thirty days was 29.5 per cent. Nine cases were improved in health two years after the operation. (3) The nine cases of continued relief presented no marked differences from the general character of all the cases. (4) The cases in which the liver was enlarged gave a lower mortality and a higher percentage of improvement than cases of atrophic liver. (5) Cases of suture of the omentum between the layers of the abdominal wall gave a lower mortality and a slightly higher percenage of improvement than cases in which only peritoneal surfaces were brought in contact. (6) Drainage increases the danger of septic infection and peritonitis and is to be avoided. If necessary, tapping may be done after the operation. (7) The presence of adhesions or perihepatitis is of good prognostic import as regards the success of the operation. (8) The number of tappings before operation and the presence of œdema of the feet and legs are of less prognostic importance than the general condition of the patient, the size of the liver, and the functional activity of the liver cells. (9) Talma's operation, or one of its modifications, is of proved benefit in a certain limited number of cases of liver cirrhosis, primarily for the relief of ascites, and, secondarily, for the relief of other symptoms of portal congestion. (10) The dangers attending the operation are mainly due to the weakened resistance of the patient rather than to the operation itself. The selection of cases suitable for operation demands more judgment than has been exercised hitherto. (11) The operation is not indicated in cases of ascites due to causes other than cirrhosis of the liver. (12) The operation is contraindicated in the presence of renal or cardiac disease, and when good evidence does not exist that sufficient functional liver tissue remains to maintain life. It is also contraindicated when complications exist sufficient in themselves to make the result of operation uncertain.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ST. BARTHOLOMEW'S HOSPITAL: ITS NEEDS AND ITS FUTURE—A CABINET MINISTER ON VACCINATION AND REVACCINATION—LORENZ'S OPERATION—THE LATE ROBERT O'CALLAGHAN AND JAMES O'SHAUGHNESSY—SOME BEQUESTS.

LONDON, January 16, 1903.

ALL the week we have been discussing St. Bartholomew's Hospital. Not only the profession, but the public have joined in the discussion, and made the future of "Old Bart's" a burning question. You must know that this hospital is the most highly endowed in the kingdom—some say in the world. Its invested property is spoken of as nearer three than two millions of pounds. For some 150 years "Bart's" has dispensed its blessings to the sick and suffering out of its own funds. Recently the governors purchased for a quarter of a million pounds a part of the adjoining land of Christ's Hospital (known as the Blue Coat School), which has been removed into the country. It was proposed to erect additional buildings on this site. It seems that the Board had not carefully counted the cost of their proposed extension, so now they have applied to the Lord Mayor to make an appeal to the public for money to enable them to build. Protests were at once raised, and have been increasing day by day. Thus there are two vigorous parties, those for and those against the proposal.

The opponents start with the statement that hitherto a Mansion House Fund has been understood to be only for cases of great emergency and unexpected calamity, and that the enlargement of "Bart's" cannot be considered to belong to that category. They add that the hospital has an income of £70,000 a year, which is more than enough to pay its way, as shown by the fact that a considerable portion of the purchase money of the Christ's Hospital land was met out of the accumulated surplus. Others suggest that the hospital should follow the example of the Blue Coat School, sell its present site, the value of which is enormous, and would suffice to buy a site with land round it, erect a magnificent, up-to-date building, and carry on the great work more efficiently than ever. It certainly looks strange for a hospital owning millions to go hat in hand to the public, and that at a time when there were never so many demands on the purses of the benevolent. But, of course, there are things to be said on the other side, and the Lord Mayor has agreed to lend the Mansion for a meeting of the governors on Monday next, on which occasion he will preside, and it may be hoped both sides will be heard. Meantime, I may quote a few expressions of opinions from the many which have already flooded the newspapers.

Sir W. Trelvar, the treasurer, says that to hint at removing the hospital is ridiculous, and pronounces the appeal necessary because they have just bought the additional land for £250,000—which hardly seems a proper reason for spending more money, still less for asking the public to find it.

Sir Blundell Maple, M.P., has no doubt that the Lord Mayor ought not to appeal for rebuilding.

Baroness Burdett-Coutts thinks the powers of the Mansion House ought to be reserved for sudden emergencies or great national objects, but does not venture an opinion as to whether the case of St. Bartholomew's falls under either of these heads.

Lord Stamford asks if it is not possible, at so late an hour, to stop the appeal?

The newspapers are mostly against the scheme. One of the most moderate is the *Globe*, which says it would be a blunder to spend money—whether from one source or another—in building on a site so enormously expensive. The *Globe* recommends the example of Paris, which is establishing central receiving stations and removing its great hospitals to healthier and less costly sites.

The managers of other hospitals join in a chorus of protests, the London Hospital leading the way. Its secretary regrets that so rich a hospital should beg while others can hardly drag on from year to year. Its chairman, Mr. Sidney Holland, has just issued his quinquennial appeal, and has hints about the extravagance of others. But people who dwell in glass houses should not throw stones"—a proverb I commend to Mr. Holland, for in the course of his appeal, while he shows that the hospital is in need of some £60,000 a year from the public, he says that it has just spent £70,000 on a new out-patient department, though he must know that the profession has long pronounced against hospital abuse, and the most of this abuse is in that department. But it is the pushing of that department which enables Mr. Holland to boast that his hospital last year treated "sixty-six and one-half miles of human beings standing side by side." It is this continual talk of num-

bers of patients on which hospital managers rely to elicit subscriptions, and this is at the bottom of much hospital abuse.

Individual doctors are shy of writing to the papers, but one pushing editor has obtained expressions of opinion by sending reply-paid telegrams. Sir H. Thompson says he has long held that all the hospitals should be supported by the state. Sir John Williams says let St. Bartholomew's get what it can. It will make good use of it. Sir W. J. Collins (an old Bart's man and on the council of the King's Hospital Fund) says the proposed extension would be extravagant, wasteful, and unwise. Sir H. R. Beevor thinks there are other hospitals in greater need.

You would not expect any of the staff of either hospital or school to advocate its removal. Behind much of the discussion the question of the school cannot fail to occur to medical men, though the subject is not brought forward. To do that would, of course, provoke an outcry in some of the sensational papers against permitting its interests to obscure that of the patients. The school buildings are modern, rebuilt within some twenty or twenty-five years, and kept up to date; but some portions of the buildings are old. Still, it hardly seems that they ought to cost £300,000. The nurses' home is inadequate, but the governors might ask themselves if it is necessary to indulge an architect with permission to erect a magnificent new one. Again, many will say that, with a cramped space, it is an extravagant thing to build a new house within the grounds for a vicar. Most of all, objections will be made to a new, enlarged out-patients' building, bad as the present accommodation is. Many complaints have been made about the out-patients at the hospital in the past, and the abuse will not decrease with larger buildings. There are other things, I fancy, might very well be excited, and a less ambitious scheme might enable the old hospital to go on until its wards have to be rebuilt, saving from its income against that day.

On Wednesday the president of the Local Government Board, Mr. Long, received a most influential deputation from the Imperial Vaccination League, with which the Jenner Society was associated. It was introduced by the president of the College of Physicians, Sir Wm. Church, and a number of eminent men spoke. Mr. Long said no one in his office would dispute the assertions made by the speakers, and the only wonder was that in this age it should be necessary for such a representative deputation to urge what should receive the support of every intelligent person. In Germany smallpox had been practically stamped out. He hoped the League, having put their hands to the plow, would not turn back. As to the new act, he could state the intentions of the government, and so furnish material to opponents. But he warned them that the strongest government could not carry legislation in the teeth of popular opposition—a curious statement that by a member of the ministry which has forced against the strongest opposition a bargain with the Church which may even yet lead to the injury of both parties to the bargain.

Mr. Long expressed full concurrence with the various points brought forward. He has shown before tenacity of purpose, and it is encouraging, therefore, to find him convinced of the necessity of vaccination and revaccination.

Professor Lorenz is here. On Saturday he gave a demonstration at Liverpool. Some of the newspapers reported the proceedings and described the manipulation and the placing of the limb in plaster of Paris after the joint had been replaced in the socket. But we do not intend to encourage this reporting. I should imagine the Chicago surgeons must have been rather sick of the fuss made, and perhaps a similar feeling may have been produced in New York. Either city has surgeons quite capable of doing all that Lorenz did, though they might hesitate to proclaim a success just after a procedure which may, after all, fail; for time has something to do with the matter. He gave a demonstration at one of the London orthopædic hospitals on Wednesday.

Mr. Rob. T. A. O'Callaghan died on Monday after a brief illness, aged forty-five years. You will remember he went to South Africa as senior surgeon to the Langman Hospital. For his services he received the medal with clasps. He devoted himself chiefly to abdominal surgery, was for some time assistant to the late Lawson Tait. He came to reside in London about eight or nine years ago. He was a Fellow of the Irish College of Surgeons, and held the appointment of surgeon and gynecologist to the French Hospital here.

Dr. James O'Shaughnessy died on Wednesday at Limerick in his ninety-third year. He was a justice of the peace for the county and a deputy lieutenant for the city. He was, I should think, the oldest magistrate in Ireland. He became a member of the Royal College of Surgeons of England in 1837. He was a schoolfellow of the late Sir Richard Quain.

Mr. E. W. Berry, who died on December 5, aged ninety-one years, has left £500 each to the London and St. Thomas's hospitals, £300 to the Royal Medical and Chirurgical Society, besides other bequests to charities. He took his first diploma in 1833. His estate is valued at £21,641.

Dr. Martin of Beckenham, who died on November 24, aged seventy-three years, bequeathed £1,500 to the Royal Medical Benevolent College, and an equal sum to Guy's Hospital. His estate is proved at £56,314.

REASONS FOR BELIEVING THAT THE ONLY WAY IN NATURE FOR YELLOW FEVER TO BE CONTRACTED BY MAN IS FROM THE MOSQUITO.

To the Editor of the Medical Record:

Sir: In my paper with the above title, as published in the Medical Record of January 24, 1903, there is a paragraph which is inaccurate, and which was not read as a part of said paper at the recent meeting of the American Public Health Association at New Orleans. The paragraph referred to begins with the fifty-eighth line of the right-hand column of page 127, and ends with the fourth line of the left-hand column of page 128. After the article had been sent to the Medical Record I discovered my mistake, and wrote and telegraphed you requesting that the paragraph in question be stricken out, but in reply was informed that the paper had already been published.

John W. Ross, M.D.,
Surgeon, U. S. Navy.

Washington, D. C., February 2, 1903.

Book Reviews.

A Handbook of Materia Medica, Pharmacy, and Therapeutics, Including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Practical Pharmacy, and Minute Directions for Prescription Writing. By Samuel O. Potter, A.M., M.D., M.R.C.P., Lond., formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco; Author of the "Quiz-Compends of Anatomy and Materia Medica," an "Index of Comparative Therapeutics," Several Articles in Foster's "Practical Therapeutics," and "Speech and Its Defects"; Major and Surgeon of Volunteers, U. S. Army. Ninth Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son & Co., 1902.

It is sixteen years since Dr. Potter's book first saw the light, and it has improved with each revision, until now it must be acknowledged to be the equal, and in some particulars the superior, of all works of the kind extant. In all books on practical medicine of the present day, the influence of a tropical climate upon pathology and therapeutics must be taken into account, and in this respect the work before us is especially valuable. For more than three years the author has been stationed in the Philippines, and the present edition contains material gathered from his experience in active practice there among soldiers and civilians, men, women, and children. The book is provided with a thumb index, greatly facilitating its use as a work of reference.

Psychic Research and Gospel Miracles. A Study of the Facts of the Gospel's Superphysical Features in the Light of the Established Results of Modern Psychical Research. By the Rev. Edward Macomb Hull, M.A., and Thomas Gilchrist Allen, M.D. New York: Thomas Whittaker, 1902.

The object of this work is to throw what is believed by the authors to be a new light upon the Gospel of Christ. This new light comes from the "superphysical phenomena" brought out by modern psychical research. As we understand the line of argument, the authors wish to show that such phenomena as telepathy, clairvoyance, certain subliminal activities, materialized psychic forms, and spirit photography are proved scientific facts, and show the existence of a spiritual realm which can control and modify the acts of man, and that it was through the interposition of this spiritual force that Christ performed His miracles and did His other wonderful works.

We can commend the very evident sincerity of the authors in their desire to put all these superphysical facts on the sound basis of exact demonstration. They think they have done it. Reading over the evidence ourselves, however, as presented here, we come to an entirely opposite conclusion. It does not seem worth while to argue over the matter in a review. The book is of interest on account of its attempt to apply the methods of science to the interpretation of an *olla podrida* of variously attested and weird phenomena. Also because the authors have collected a great many curious stories and alleged facts regarding manifestations of spiritualism. The marvel is that those who can write in some lines so well show such curious defects of judgment in the end.

NEW YORK ACADEMY OF MEDICINE.

Section on Surgery.

Stated Meeting, Held January 12, 1903.

John B. Walker, M.D., Chairman.

Gastroenterostomy; Gaping of Abdominal Wound.—Dr. H. D. Collins presented an elderly woman upon whom he had performed gastroenterostomy. The subjective signs were vomiting and pain. Examination of the contents of the stomach showed an absence of hydrochloric acid. The incision was made in the median line, and an anastomosis was made, with the help of a Murphy button, between a loop of jejunum and the posterior aspect of the stomach. It was a simple, straight anastomosis, the intention being to make another anastomosis at a subsequent stage of the operation, and in this way avoid a vicious circle. However, the patient's condition was so poor that it was not thought best to do any further operating at the time. She was fed by rectal enemata, absolutely nothing being given by the mouth for the first three days. She then complained so bitterly of thirst, that she was given sterile water by the mouth. On the fourth day she was allowed to have peptonized milk, the rectum being somewhat intolerant. On the sixth day examination of the wound showed its condition to be apparently absolutely perfect. The skin sutures were, accordingly, removed. That evening it was found that the entire abdominal wound had opened up, and showed no evidence of repair. She was anæsthetized by the house surgeon, and the hand introduced into the abdomen showed the button in place, but no evidence of adhesions. The abdominal wall was again sutured by layers, and after that healing was satisfactory. The second day after this second operation, vomiting began, and lasted for a considerable time, but in other respects she did well. The operation was done on September 5, and, although a careful watch had been kept, nothing had been seen, as yet, of the button. The patient's general condition had improved greatly since the operation.

Dr. H. Lilienthal said, regarding the separation of the wound so long after the operation, that he did not believe this was of infrequent occurrence; he had had the misfortune to encounter it in three cases, all of them gastroenterostomies. All of the patients were cachectic, and in bad physical condition, and this probably explained the slowness of repair. In one of his cases the wound broke open ten days after operation, and another case, eight days afterward, breaking through the sutures. He thought the stout sutures of forty-day chronic gut should be put through all the tissues except the skin. It would be well, also, to roughen the peritoneum before introducing the sutures.

Dr. Robert T. Morris said that this separation of the wound was very interesting. The only case of the kind that had occurred in his practice was in a patient upon whom he had operated ten days ago. The patient was emaciated, and had had obstruction for two or three years following a perforating ulcer of the stomach. Everything appeared to be doing well until about two weeks after operation, when the use of the stomach tube was begun. The first attempt of this kind resulted in tearing the wound entirely open.

Dr. George E. Brewer said that two or three years ago he had had a patient at the City Hospital with œsophageal carcinoma. Gastrostomy was done through a small wound, and three or four sutures of silkworm gut were inserted. After ten or twelve days, the wound appeared to be healed, and the sutures were removed, but it was found that there was only adhesion of the skin.

Dr. A. V. Moschcowitz reported three cases, all gastroenterostomies. One was still in the service of Dr. A. G. Gerster, and in that one the entire wound burst open on the eighth or ninth day, as a result of the patient's making a sudden movement in bed. The speaker said he now made it a rule to remove the stitches in such cases as late as possible.

Dr. J. A. Blake referred to a case that he had seen in the hospital service of Dr. Bull. The wound opened on the sixth day. This patient was very cachectic, and the operation was for a carcinoma of the stomach.

Dr. John F. Erdmann said that in a case upon which he had operated for volvulus and tuberculous peritonitis, the wound opened on the ninth day, and this, too, despite the fact that he had taken special pains in coaptating the parts at the time of operation.

Dr. John B. Walker reported the case of an emaciated woman with an echinococcus cyst. Ten days after the operation, the wound appeared to have healed completely, and the sutures were removed. A few days later, the wound suddenly opened during a spell of coughing. It was brought together again with adhesive plaster, and then healed without further trouble.

Dr. Edward M. Foote reported a case to show that this accident might occur in other parts of the body. He recalled a case of partially pedunculated carcinoma of the vulva, in which the inguinal glands on both sides were infected, and were dissected out. The stitches about the vulva were left *in situ* for twelve or fourteen days, but on removing them there was found to have been absolutely no effort at repair, the wound appearing like a fresh one.

Stenosis of Stenson's Duct.—Dr. Collins also presented a man who had come to him last May with a swelling over the region of the right parotid gland. There were present all of the usual evidences of abscess, and the house surgeon made an incision anteriorly, and evacuated pus. This operation was followed by the discharge of saliva from a sinus. When seen by the speaker, the introduction of a probe showed that the sinus extended upward and forward for a considerable distance. A probe passed in from within the mouth went up near to the upper end of the sinus, but terminated on a different level. An incision was made in such a way as to allow each probe to protrude through the incision. Each probe was threaded, and a continuous silk seton was introduced through the mouth, and the duct, and outside of the cheek. Once or twice a day this silk was drawn backward and forward a few times. After a few weeks the seton was removed, and then Stenson's duct was probed daily. The depth diminished little by little, and the interval of the probings was gradually increased. The outer opening closed quite promptly. The original cause of the abscess was unknown, but quite probably there had been a blocking up of Stenson's duct, with subsequent infection.

Dr. Frederic Griffith reported a case in which a ragged tooth caused ulceration through the cheek and a salivary fistula. Following the method of Hayes Agnew, he had made use of a silk thread ligature, extending about the duct from within the mouth almost to the skin surface. This cut its way through in the course of three or four days, making a new outlet.

Localized Enlargement of the Left Lobe of the Liver Due to Cirrhosis.—Dr. Charles H. Peck presented a man, forty-two years of age, who four years ago began to suffer from a peculiar sensation of discomfort in the stomach. This had continued ever since, and the man had lost about fifteen pounds during these four years. About two years ago a swelling was noticed in the epigastrium, and it had not changed materially in size. On admission to hospital on December 22 examination showed a rounded swelling in the epigastrium. This could be felt just above the edge of the left lobe of the liver. It was thought to be a cyst or some other benign growth. An exploratory operation was done two weeks ago. The under surface of the left lobe showed no tumor whatever, and the edge was sharp, and presented distinctly the appearance of a cirrhotic liver. The right lobe of the liver presented the same characteristic appearance without much enlargement. The liver was

punctured in several directions, and was thoroughly explored, but nothing was discovered except the cirrhotic liver tissue. He, therefore, looked upon the tumor as a localized enlargement of the left lobe of a cirrhotic liver.

A Peculiar Case Simulating Cholelithiasis.—Dr. H. Lilienthal presented a man of twenty-eight years who had been admitted to the Mount Sinai Hospital on December 26, 1902. His previous history was absolutely negative. The present illness began very suddenly with cramps in the abdomen and severe vomiting of a blackish material. He had been drinking to excess at the time. He complained specially of a constant pain in the right hypochondriac region. This pain did not radiate, and was not associated with chills, or with a temperature above 100° F. There was no jaundice, and the stools were normal. On admission he was fairly nourished, and there was a marked icteric hue to the face and conjunctiva. On examination a distinct cup-shaped process could be felt in the right hypochondrium, extending as far down as the umbilicus, and extending between the left rectus and the mammary line. The case seemed to be absolutely typical of cholelithiasis with a stone impacted in the cystic duct. The mass found on examination was globular and was extremely tender. On December 27 a small longitudinal incision was made through the upper part of the right rectus, and this revealed a mass of dense adhesions. The tissues were matted together by recent lymph in such a way as to suggest the presence of abscess. The edge of the liver was peeled off, then the stomach and the duodenum, and, finally, a perfectly normal gall-bladder was exposed. The mass was then seen to be in the hepatic flexure of the colon. The colon was freed by blunt dissection, and was found to be decidedly thickened. On account of the acuteness of the process and the patient's condition, further operation was deemed inadvisable. The man made a perfect recovery, but the cause of the mass of adhesions was still a mystery. It was not in the pylorus or in the liver, and the gall-bladder was perfectly normal. Undoubtedly the trouble, whatever it was, was situated in the colon.

Dr. Blake thought the case might be one of foreign body in the colon, for he had removed a fish-bone from the ascending colon after it had given rise to much the same disturbance.

Dr. Walker recalled the case of a man who had swallowed a portion of a bent hair-pin that he had been using for the application of cocaine to the nose. An incision was made over the mass in the ascending colon, and it was found to be surrounded by adhesions, as in the case just reported. The hair-pin was found and removed.

Results of X-Ray Treatment.—Dr. P. R. Turnure read this paper, which was based on observations extending over a period of two years at the New York and Roosevelt hospitals. The total number of cases treated at the Roosevelt Hospital during the last twelve months was ninety-four, but he had been able to follow and keep satisfactory records of eighty-two. He had made use of three different coils, each one more powerful than the preceding. At present he was using a twenty-inch coil, and preferred this one, because the results seemed to be more quickly obtained with it. He had been unable to formulate any general rule about *x*-ray tubes further than that the resistance should be low, and the tube should be able to carry a large quantity of current without changing its vacuum. An exposure of five or ten minutes was given, and the method preferred was to give the exposures every day for the first week, then every other day for the second week, and then after an interval of two weeks resume the treatment as before. He had had five cases of epithelioma of the nose, all of which had done well. One now under treatment, after eight exposures, showed marked improvement. There were three cases of epithelioma of the lip. One of these had done badly after a vigorous *x*-ray treatment for fourteen days. The treatment caused deep sloughing. He had had two cases of epithelioma of the penis, one of which only had done well. The general results in all of the epitheliomas were good, and he thought the *x*-ray treatment was indicated in these before operation. The results were quite different in carcinoma. He had had five cases of carcinoma of the neck, and ten cases of carcinoma of the breast, three of the latter being primary. Two of these were absolutely inoperable. Of the seven recurrent carcinomata of the breast only one was successful to any extent. All of them, after a short period of improvement, seemed to follow the natural course of the disease. This temporary improvement could be noticed in all cases, and he attributed it solely to the psychic effect of the new treatment. Sometimes this lasted as long as six weeks, and then the disease progressed as before. In one case, to which great attention had been given, the disease spread quite rapidly, the progress of the disease actually seeming to be stimulated by the *x*-ray. In two cases of sarcoma, one of the limb and the other of the neck, the pain was relieved for a few weeks. He had only treated three cases of tuberculous glands of the neck, and all of these were in children. All of them improved greatly after four weeks of treatment, but all of this improvement he attributed to the good care the children received while in the hospital. Two cases of tuberculosis of the larynx were treated, one for four and the other for six weeks, without any improvement. Two cases of lupus were treated, one for eight and the other for twelve weeks. They appeared to have been cured. Three cases of erythematous lupus were treated. Two did extremely well, though both of them required over four months' treatment. The third, after seven months of treatment, was only slightly improved. Five cases of chronic eczema of the leg were treated by the *x*-ray, and all were cured apparently as a result of the irritation produced; nevertheless, the treatment was much slower than other well-known methods. It was worthy of note, however, in this connection, that the itching ceased very promptly after the *x*-ray treatment. Dr. Turnure said he had treated one woman with the *x*-ray for the purpose of removing hair from her face. The treatment had been carried out very cautiously, and after four months the hair had been entirely removed from the area treated without any burning. If this result proved to be permanent, he would treat the rest of her face, because the woman had tried the electrolytic method and had found it very painful.

Conclusions.—The results that he had observed in *x*-ray treatment were certainly confusing, but the first thought that occurred to him on studying these records was that *x*-ray treatment, to be successful, must be used upon superficial disease processes. If the *x*-ray exerted its influence very deeply, it was almost certain that some of these effects would be observed in *x*-ray workers, which, so far as he knew, was not the case. Glands, which were often secondary to epithelioma, were not really epitheliomatous deposits, but were the results of secondary infection. The speaker said he was extremely sorry to have to report such poor results, for, a year or more ago, he had been very enthusiastic over *x*-ray treatment. Undoubtedly, many cures were effected in superficial growths. Most of these cures appeared to be permanent, but he had had one recurrence take place eight months after what appeared to be a perfect cure.

Dr. H. Lilienthal said that he had watched some of the cases treated by the *x*-ray at the hospital. He had, apparently, seen epitheliomata cured, but he had never seen a deep growth cured by the *x*-ray alone. At present, he had under his care a small round-cell sarcoma of the scapula, which had been proved to be of the malignant type. Through a generous incision, a piece had been removed for examination. Ordinarily one would not expect this incision to heal, but under the use of Coley's fluid and of the *x*-ray there had been a gradual flattening of the tumor, the wound had healed promptly, and the

skin had become markedly pigmented. Of course, Coley's fluid was used here, and while there was only one reaction from this, and that might have been an accidental infection, she was now taking enormous doses of this fluid without any reaction. This patient had been exposed to the *x*-ray for fifteen minutes on alternate days. The case had been doing so well that he had not felt called upon to operate. Dr. Coley was of the opinion that his fluid only benefited when it caused a reaction; if this were true, then it might be very properly argued that in this case the good result was due to the *x*-ray and not to Coley's fluid. While the results reported in the paper were disappointing, it was quite possible that we had been altogether too optimistic regarding this agent; for, as a matter of fact, we knew very little about it. The *x*-ray treatment at the present time should be reserved for inoperable cases.

Dr. Robert T. Morris agreed with the last speaker that, in this experimental stage, only inoperable cases should be subjected to the *x*-ray. He had had one case of lupus of the forehead, which was practically well, and a case of epithelioma of the lip in which the cervical glands had been so much involved that he thought operation was not indicated. The latter case was now apparently well. In a case diagnosticated as inoperable sarcoma of the parotid, the *x*-ray treatment had, apparently, produced a complete cure. In another case of very extensive recurrence in the glands of the neck, after amputation of the breast, some improvement had been effected, but the patient had not followed the treatment very closely. He was disposed to feel, as did the reader of the paper, that the *x*-ray was not of great value where the malignant disease was deeply situated. He had one case of epithelioma of the trigone of the bladder that was being treated by the *x*-ray by way of the rectum and a suprapubic incision. At last accounts the case was decidedly better. A very interesting point was, that neoplastic deposits in the glands seemed to disappear under the influence of the *x*-ray.

Dr. Carl Beck said he was convinced that if sufficient treatment were given to any epithelioma it could be cured, but he also believed this was not so good a method as thorough extirpation of the epithelioma by the knife. The *x*-ray should be reserved more especially for special cases, as, for example, epithelioma of the eyelid, where a particularly good cosmetic result was desired. He had seen a number of cases in which the disease had recurred just as rapidly after *x*-ray treatment as after operation. Last spring he had presented to a medical society an old man in whom an epithelioma of the upper eyelid had been completely cured by twenty exposures to the *x*-ray, yet very shortly afterward the disease appeared in the upper lip, showing how widely disseminated were the cancer cells. The use of protective shields was a mistake, because our object should be not only to have the *x*-ray tube as near as possible, but to secure a wide effect. He had noticed that those who used the *x*-ray very carefully, in the hope of avoiding burns, were the ones who obtained only indifferent results. It was often well to run considerable risk of burning the patient. He had met with cases in which improvement had only been effected after the use of very strong doses of the *x*-ray. He would not advise the treatment of carcinoma of the stomach and of the bladder by the *x*-ray, on the principle that it was unwise to leave for the *x*-ray what could be done by the scalpel. He believed that there was not a case of lupus that would not yield to the *x*-ray.

Dr. Thomas H. Manley complimented the author of the paper on his practical and candid treatment of this subject. He thought the paper and the discussion showed clearly that the sphere of *x*-ray treatment should be limited to the treatment of lupoid growths. What had been said about the disappearance of glands bore out his own experience, that when the local source of irritation or infection was destroyed the glands would take care of themselves.

Dr. Turnure closed the discussion. He said he wished to make clear the fact that one of the cases, indeed the one that had apparently given the best result, had already recurred. He was not in a position to say at present how many recurrences there would be. The scar on the face from *x*-ray treatment had been found much less disagreeable than the scar usually left after a cutting operation. His experience had been that the recurrence from operation was greater than from the *x*-ray. This was his present opinion, although it was quite possible that he might have reason to change that opinion in the near future. The result in the removal of hair from the face was certainly far better than from electrolysis.

Improved Gigli Saw.—Dr. A. V. Moschcowitz presented this instrument, along with a frame and handle that he had devised, so that the saw could be readily used in every direction. He said that the ordinary Gigli saw was a wire upon which had been turned a thread; in reality, therefore, one was always sawing with this instrument in a part of a circle, and for this reason the action of the saw was very slow. This difficulty he had overcome by having a second turn made upon an ordinary Gigli saw. This turn was much shallower than the ordinary thread, and divided the latter into a number of fine threads. He had found that this improved saw would saw about six times more rapidly than the ordinary Gigli saw.

A Complete Portable Operating Case.—Dr. A. A. Berg presented, on behalf of Dr. A. G. Gerster, a portable operating case, which was believed to contain every instrument necessary for the performance of major surgical operations.

Officers Elected.—Dr. Robert T. Morris was elected chairman, and Dr. Charles H. Peck, secretary, of the section.

NEW YORK PATHOLOGICAL SOCIETY.

Regular Meeting, Held December 10, 1902.

Cholesterin Giant Cells.—Dr. F. S. Mandlebaum showed specimens of giant cells caused by cholesterin in granulation tissue. Dr. Mandlebaum said that he had met this condition in but two cases and deemed the matter of sufficient importance to bring before the Society. The first case was that of a woman of thirty who had a small, probably congenital, prethyroid cyst. The cyst wall had a granular, honey-combed appearence and was covered with an exudate. The second case was that of a cyst of the breast in a woman of fifty who had had the condition for ten years. Recently the cyst had begun to enlarge and a sinus was formed which discharged a thick yellow-colored fluid. The cyst wall was covered with a shaggy, dark reddish exudate, somewhat granular and friable in character, and easily separated from the cyst wall. This exudate measured about one-half to one cm. in thickness. Sections of this cyst and of the first case showed the following conditions: The first thing noticable was a large number of slit-like openings, elliptical in shape, pointed at both ends, and very sharply defined, which looked as though they had been punched out of the tissue with a sharp instrument. The next thing noticeable was the large number of giant cells scattered throughout the whole section. They were of the kind generally seen in inflammatory processes, very large in size, and containing thirty or forty nuclei scattered throughout the cell body. These were rich in chromatin and stained very deeply. Within the body of many giant cells these small elliptical slits were also noticed. In some there were two such clefts. The rest of the tissue was made up of inflammatory tissue, vascular and connective tissue. Many of the giant cells contained coarsely granular pigment. A study of the sections proved that these slit-like openings were produced by cholesterin, which in tissue does not take the form usually seen in fluid exudates, but appears in these elliptical

shapes. Dr. Mandlebaum's impression was that the cholesterin was present in combination with fatty acids. The specimen naturally went through alcohol and ether which extracted the cholesterin. This explained why one did not discover the cholesterin crystals themselves which are in the tissue, but simply the clefts out of which they are extracted. The alcohol is usually thrown away so that chemical tests cannot be made of it. Nevertheless Dr. Mandlebaum made such tests but did not get any reaction for cholesterin. He then took a bit of tissue from the second case and macerated it with chloroform, and from this solution obtained crystals which resembled those of fatty acids. These crystals and also bits of the tissue itself, gave reactions for cholesterin. There was the usual play of colors when treated with sulphuric acid and ferric chloride and the violet color remained. One would imagine that these cholesterin crystals ought to present the familiar appearance described; they do not, however, as many complex changes undoubtedly occur due to various chemical unions. Sections of both cases were shown and also slides showing the fatty acids obtained by evaporating the chloroform in which parts of the specimen had been macerated..

Dr. Wood asked whether Dr. Mandlebaum had made tests on other sections so as to eliminate the possibility of these color reactions having been produced by the action of the strong acid on the proteid of the section itself.

Dr. Mandlebaum said that these tests had not been made. He did not know whether the ordinary proteid would give that reaction in strong sulphuric acid, and whether that obtained might be due to it. He had made other tests with sulphuric acid and with the addition of small quantities of iodine and got both reactions. He was inclined to think these were conclusive. He had also evaporated the extracted chloroform and so got a reaction. It was not quite so marked with the nitric acid and ammonia test.

Glioma of the Brain.—Dr. T. C. Janeway presented this specimen of glioma of the cerebellum, not, he said, because of its remarkable rarity, but because the case had a very characteristic history and ran an unusually rapid course. The specimen was obtained from a man of forty who entered St. Vincent's Hospital on the 25th of October. He gave the following history: He had been a moderate drinker and had chancroids; beyond this there was nothing of any particular importance in his past history. On Labor Day his first symptoms of brain trouble appeared in the form of an attack of dizziness while in a parade. He was compelled to rest and return home. The same day he traveled to Newburg, and while there he fainted and had a repetition of the vertigo. From that time the attacks of vertigo succeeded each other, coming several times a day, and he began to stagger and to run into objects. He had severe headaches, which were very much intensified by any movement. The pain at first was all over the head, but in the latter part of his illness was confined to the right side. He had attacks of vomiting which he referred to taking milk. He was sent to the hospital with a diagnosis of brain fever. On admission he had staggering and exaggerated reflexes, both of the patella and of the arm. The temperature was normal. The right pupil was dilated. Dr. Callan reported optic neuritis which was more pronounced in the right eye. He had perfect control over his bladder and rectum. From that time until December 6, when he died, he was put upon mixed treatment. He was seen by the different attending physicians, and by Dr. Starr, and the clinical diagnosis was made of gumma of the cerebellum. He improved for a time, but the improvement soon ceased and he became delirious, vomited freely, had intense headache, and died rather suddenly. At autopsy the following condition was found: He had a fairly-marked flattening of the convolutions all over both hemispheres. There was a marked flow of fluid on opening the lateral ventricles. Section of the cortex showed nothing particularly abnormal. On opening the cerebellum in the median line one came upon a small irregular cyst filled with yellowish contents, surrounding which was a narrow area of tissue which was hardly demarcated from the normal white matter of the cerebellum in which it lay, except that it seemed to be a little firmer than the rest of the tissue. The lower part involved the right superior peduncle. This portion was in color very much like the normal tissue; there was no distinct line of demarcation. The ragged cyst in the center was filled with yellow contents which showed broken-down granular detritus. Sections from the edge showed perfectly typical glioma with very numerous thin-walled blood vessels. Sections from the peduncle showed very cellular glioma with occasional ganglion cells scattered throughout, which were apparently inclusions in the tissue. A point of interest was whether the initial symptom was due to hemorrhage into the solid portion of the tumor and whether the glioma had been of more than two-months' duration.

Dr. Harlow Brooks said that it seemed to him rather remarkable, from the location of the tumor, that it could have existed long before the onset of the first symptoms. He thought that glioma of the brain often grew very rapidly. In his experience glioma of the cerebellum was much rarer than gloma of the cerebrum.

Dr. Fraenkel said that in his experience glioma of the cerebellum was much rarer than in other portions of the excephalon.

Demonstrations of Cultures of the Meningococcus and Micrococcus Catarrhalis.—Dr. H. C. Cellar gave the results of investigations made during the last five years at the laboratory of Mt. Sinai Hospital on about twenty cultures of the diplococcus intracellularis of Weichselbaum.

Morphologically the meningococcus appeared as a diplococcus, the contiguous sides of the individual members being flattened and separated by a fine line of division appearing as an unstained area under the microscope. There was a marked tendency to form tetrads, but the chain formation described by Heubner, Jaeger, and others, was not seen. It was common to find great variations in the size of the individual cocci, large forms appearing next to small ones, especially in older cultures. All of the cultures were invariable decolorized by Gram's solution; none of the non-decolorizing form of Heubner being met with. The organism showed no capsule. Growth on agar was not constant. Some of the cultures grew upon this medium at first but later lost this power, while others showed a gradually increasing profuse growth and could be readily kept alive by transplanting to fresh tubes at intervals of a few days. The addition of human serum—ascitic, pleural, or hydrocele—to the agar always gave better results, but the most luxuriant growth was obtained upon the medium devised by Dr. Libman, serum agar plus glucose ($\frac{1}{2}$ to 2 per cent.). Maximum growth was obtained with the higher percentage of glucose. With the addition of still higher percentages of glucose (3, 4, 5 per cent.) as well as with the use of lactose or saccharose (2 per cent.) the development of the organism was neither furthered nor hindered, On Loeffler's serum there was an abundant growth, but there was no advantage over the serum glucose media. On glycerin agar the growth varied, usually only a few fine colonies being obtained; but on the addition of serum the growth was profuse. In fluid media the organism grew characteristically. The growth began as a diffuse cloudiness near the surface that after two or three days formed a white scum on the surface. The remainder of the medium was at first clear, later slightly clouded, while at the bottom of the tube there was a floccular sediment. There was considerable difficulty in obtaining growth in this form, as the shaking of the tube would

prevent the formation of the scum or cause it to break up and fall to the bottom after it had formed. The majority of the cultures grew slightly in ordinary bouillin with and without the addition of sugar in the form of glucose, lactose, or saccharose. Some, however, grew only upon the addition of serum; the sugar in these cases having apparently little advantageous effect. There was no gas formation in these media in the Smith fermentation tubes, in which growth was confined to the bulb. In litmus milk growth was demonstrated. The milk was not coagulated, and there was no acidity production. On gelatin there was no growth at room temperature. On potato the results varied. Sometimes there was no growth, while at others there was a delicate film on the surface that was seen with difficulty or could only be demonstrated by scraping the surface of the medium. Anaerobically there was no growth. Almost identical morphologically with the meningococcus, but differing from it culturally, was another organism found in normal and some pathological conditions on the mucous membranes of the respiratory tract, in the eye, the ear, and, occasionally, the urethra. This was the micrococcus catarrhalis of Ghon. The culture studied was obtained through Dr. Buerger of the German Hospital and was isolated from a throat culture. In spreads this organism appeared as a diplococcus with some flattening of the adjacent sides of the cocci. It decolorized with Gram. There was no capsule. In all its characteristics it bore so close a resemblance to the gonococcus that it could be differentiated therefrom under the microscope only with great difficulty. The tetrads formed by the meningococcus, as well as the large forms already described, would sometimes serve to differentiate this from the other two organisms. Further, the individuals of the micrococcus catarrhalis were more nearly oval than those of either the gonococcus or the meningococcus. On agar the micrococcus catarrhalis grew profusely, even in the first generation, herein differing from both the meningococcus and the gonococcus, that showed either no growth or very slight growth on this medium. The use of glycerin or serum agar, Loeffler's serum, or Libman's serum media afforded no particular advantage. In fluid media the scum formation already described was readily obtained if the cultures were not disturbed. The membrane lacked the homogeneity of that formed by the meningococcus, being composed of dry granular clumps floating on the surface. In the variation in the cloudiness of the medium as well as in the floccular sediment the two organisms were identical. There was no gas formation in glucose, lactose, or saccharose bouillon in fermentation tubes; growth was confined to the bulb. Acid production in glucose and saccharose bouillon was demonstrable. In litmus milk there was growth without coagulation or acidity production. On gelatin there was no growth at room temperature. Ghon reported slight growth after five or six days under proper thermal conditions. On potato growth was fairly luxuriant, older cultures appearing yellowish brown, the water remained clear. Anaerobically there was no growth. On plates the meningococcus and micrococcus catarrhalis were readily differentiated. The superficial colonies of the former were light brown; there was no nucleus, but at the center were large clumps that gradually diminished in size toward the periphery. The outer zone was finely granular and paler in color. The edge was sharply defined, circular, and regular. There was a very close similarity between these colonies and those of the gonococcus. The colonies of the micrococcus catarrhalis were dark brown in color, lighter at the periphery. The older colonies showed a distinct dark nucleus, the remainder of the colony being finely granular. The edge was sharply defined and circular, but differed from that of the meningococcus in being irregular, as though gnawed. Macroscopically, the nucleus of the colonies of micrococcus catarrhalis and the white lacquered surface, as compared with the absence of nucleus and the grayish-white surface of meningococcus colonies, served to distinguish between these two organisms. A most important means of differentiation was furnished by the nature of the growth both on slants of solid media and on plates. On the former the meningococcus presented a shining grayish moist growth that was viscid, stringy, and readily scraped from the surface. The growth of the micrococcus catarrhalis, on the other hand, was white, dry, crumbly like mortar, and adhered to the surface of the medium. Sometimes the entire growth could be removed as a membrane. On plates the same differences were seen. The viscidity of the meningococcus colonies stood in marked contrast to the dryness of the colonies of micrococcus catarrhalis, that slid along the surface of the medium without breaking up. The experiments were limited to inoculations into white mice, guinea-pigs, and rabbits. Subcutaneously both organisms were without effect. In a small proportion of cases intraperitoneal and intrapleural inoculations of either meningococcus or micrococcus catarrhalis in mice and guinea-pigs proved fatal. Autopsy showed a serofibrinous peritoneal and a hemorrhagic pleural exudate. A splenic tumor might or might not be present. All the viscera showed hyperæmia and degeneration. The organism could be recovered from the exudates and sometimes from the blood and spleen. The virulence of the micrococcus catarrhalis was far less marked than that of the meningococcus. Larger animals were less susceptible. In rabbits intravenous (Ghon, Weichselbaum) and intracranial (Weichselbaum) inoculations of the meningococcus proved fatal. Injections into the meninges of goats with the production of meningitis had been successfully carried out by Heubner and by Councilman, Mallory, and Wright.

Remarks on the Meningococcus, and on Its Relationship to the Gonococcus and Micrococcus Catarrhalis.—Dr. E. LIBMAN made some remarks on these organisms in connection with the demonstrations by Dr. Celler, particularly with the idea of attempting to throw some light on the questions in dispute. During the past five years he had had the opportunity of studying bacteriologically over one hundred cases of menengitis. In most of these the fluid obtained by lumbar puncture intravitam was examined; in a few examinations were made at autopsy only. In these cases he had had the following results.:

Tuberculous cases	44
Streptococcus cases	17
Pneumococcus cases	6
Staphylococcus aureus cases	3
Pseudo-influenza bacillus cases	1
Proteus vulgaris cases	1
Bacillus pyocyaneus cases	1
Diplococcus meningitis cases	20

In a few cases streptococci and a variety of bacilli were found; the last could not be grown aerobically. It was suspected that these were anaerobes, particularly as all these cases were secondary to mastoid disease. The cases occurred in all the services of the hospital; a few were cases from the private practice of Dr. Libman and other physicians. (The larger number of cases due to the meningococcus occurred in Dr. Koplik's service.) Dr. Libman then briefly stated their opinions on several mooted points, based on a study of these cases.

1. As to the relationship of the pneumococcus and the meningococcus from an epidemiological standpoint: All the pneumococcus cases were secondary. Observations recorded in the literature would seem to indicate that the pneumococcus could cause epidemic meningitis. It was to be noted that any pathogenic organism might produce a meningitis as the only evidence of a systematic sepsis; and an organism might cause a meningitis by first causing an otitis media or a small area of pneumonia. If the primary disease led in a short time to a menin-

geal inflammation, the case clinically corresponded to a primary meningitis. One of the pneumococcus cases studied was characterized by an acute meningitis following within less than twenty-four hours an apparently mild otitis media without pus production.

2. There were on record descriptions of a number of varieties of the meningococcus (Heubner, Jaeger, and others). Some corresponded to what Weichselbaum described. Others differed in holding the Gram stain, in the profuseness of their growths on ordinary agar and bouillon, or in their growth on gelatin media, etc. All of Dr. Libman's cultures corresponded with those described by Weichselbaum. None of them ever showed Gram-positive diplococci. There was a variation of the growth on media not containing serum; but it was never profuse. He only once obtained a growth (very slight) on gelatin at room temperature, and hardly any or none on potato in the incubator. According to his experience then there was but one type of the diplococcus meningitidis in the New York cases of cerebrospinal meningitis. Councilman and Wright found the same in Boston, Olser and Hirsch in Baltimore, and Herrick and others in Chicago. They were inclined to believe that there was but one type of organism at play in the European cases. The description of other varieties was believed to be due to one of three causes: (a) Variations in the use of the Gram stain. (b) Use of other methods for differential staining. (For instance, Heubner uses a Gram-Weigert stain.) (c) The occurrence of skin contaminations (staphylococci).

3. If it were not for a statement in Leube's book on diagnosis (last edition) it would hardly be necessary to point out that the pneumococcus should not be confused with the meningococcus. Leube said that animal experiments are necessary for the identification of these organisms. If it be granted that the meningococcus did not hold the Gram stain there was a fundamental difference. The pneumococcus was lancet-shaped, has a capsule, diffusely clouded bouillon, grew much less profusely than the meningococcus in serum media, etc.

4. As to the occurrence of the meningococcus in the nose and throat it was found several years ago that other diplococci occur in the nose and throat which resembled the meningococcus morphologically and in staining reactions. In one case reported by Dr. Koplik, Dr. Schwarz found the meningococcus (proven culturally) in a conjunctival inflammation which was followed by a fatal attack of meningitis. The meningococcus was repeatedly found in the cerebrospinal fluid.

5. Dr. Libman considered the demonstrations made by Dr. Celler of prime importance not only with regard to the undoubted confusion the micrococcus catarrhalis had caused with regard to the meningococcus, but also because it could be easily mistaken for the gonococcus if cultures were not made. It had been repeatedly seen in cultures from the throat and in sputum, and once in otitis media. It had been found in the urethra and probably in the conjunctival sac. The culture of the micrococcus catarrhalis demonstrated corresponded to those described by Ghon and Albrecht (*Zeitschrift für klinische Medicin*, Vol. 44). Dr. Libman was convinced that this is but one of a group of closely allied organisms.

6. Since Dr. Celler has shown how the meningococcus could at times closely resemble the gonococcus culturally, it was important to differentiate the organisms carefully; this was true not only from a mere technical standpoint but also because the question may arise clinically. Fraenkel had described meningococcus-like organisms in conjunctivitis. Furbringer reported a case in which cerebrospinal meningitis occurred in a patient with gonorrhœa. The meningococcus was found in the puncture fluid and apparently (cultures not made) the gonococcus in the urethral discharge. There were also reported two cases in which the meningococcus was found in the blood; in one long before symptoms of meningitis were manifested. In such cases as this last careful methods should be used before the identity of the organism is established. Special stress was laid on these points:

(*a*) The occurrence of tetrads and the irregularity in size and staining reactions.

(*b*) The profuse growth of the meningococcus in Loeffler's serum and the absence of any growth of the gonococcus on this medium. Some claimed to have seen a very slight growth of the gonococcus.

(*c*) Dr. Libman never obained growth on the gonococcus in agar. At times the meningococcus grows on agar. Some writers had noted slight growths of the gonococcus on agar. In any event a good growth on agar spoke against the gonococcus.

In serum bouillon media and serum glucose bouillon media, the two organisms grew practically in the same way. It was repeatedly noted that the growth of the gonococcus in fluid media, if the observations were carefully made, was on the top of the fluid in the form of a white scum. This feature of the gonococcus had, as far as he knew, never before been described.

7. None of the three organisms under discussion caused precipitation in any of Dr. Libman's serum sugar media. According to his experience, staphylococci always precipitated in 2 per cent. glucose serum agar. By the use of this medium the occurrence of the confusion of staphylococci with meningococci, which Ghon and Albrecht suspected in some of the reported observations, could be avoided.

8. As to the frequency of finding the meningococcus in cases of cerebrospinal meningitis, Dr. Libman had studied thirty cultures in twenty cases (in some, repeated examinations were made). In all cases the diplococcus was found in spreads or in cultures. In the first seven cases they failed to obtain the organisms culturally in one. In the last seventeen cases positive cultural results were always obtained. At times the organisms were found in spreads at first, but not later. Cultures might be positive first and negative later. They believed the diagnosis could always be established if the examination were made early. In cases of long standing, cultures and spreads might be found negative.

9. Results were obtained with small amounts of fluid when the 2 per cent. serum glucose agar was used. Usually ½ to 1 c. cm. of fluid was poured into a tube of the medium. Twice a day the condensation fluid and added fluid were allowed to flow over the surface of the medium (Heubner's method). It often required forty-eight hours for a result. Once it required seventy-two hours. The occurrence of a growth of a Gram-negative diplococcus, which showed no or but slight growth on agar, no growth on gelatin nor on potato nor on bouillon in twenty-four hours, which caused no change in litmus milk in the same time, and which grew profusely on Loeffler's medium was sufficient to make the presence of the meningococcus a certainty. These final remarks held true provided media of certain titers are used. From his experiences Dr. Libman thought that the media not containing serum should be neutral or slightly alkaline to phenolphthalein. The serum media should be made from agar, which is ½ or 1 per cent. acid. The subject of the titer was of extreme importance with regard to the meningococcus and gonococcus.

Dr. Harlow Brooks said that some years ago he had studied a series of cases of purulent meningitis. This was before Dr. Libman's culture media had been devised. He became so mixed up with the various forms of meningococci that he had never dared to publish the results. He had found it very difficult to differentiate at times between the meningococci and the micrococcus catarrhalis. He also found that animal experiments were very uncertain. He found that large quantities of culture were usually required in order to obtain growths of the

meningococcus. He thought that Dr. Libman and Dr. Celler's work was most important and would be particularly appreciated by those who had done any work with these organisms.

The Influence of Nephrectomy on Absorption.—Dr. William Salant of the Rockefeller Institute for Medical Research read a paper by Dr. S. J. Meltzer and himself on the influence of nephrectomy upon absorption, in which they gave the results of their studies upon absorption from the peritoneal cavity of nephrectomized and normal rabbits. They began by injecting an .8 per cent. salt solution, which was allowed to remain in the peritoneal cavity for from one-half to nineteen hours. Injection was made immediately after nephrectomy. It was found, contrary to expectation, that absorption was much better in nephrectomized than in normal rabbits. In normal rabbits the average per cent. of absorption per kilo. was 43 per cent., while in nephrectomized rabbits it was 65 per cent. Since these results might be due to the rise of osmotic pressure in the blood of nephrectomized rabbits, several series of experiments were undertaken with salt solutions of higher concentrations. The next series of experiments was performed with 1 per cent. salt solution, which was allowed to remain in the peritoneal cavity for one and one-half hours. Absorption in normal rabbits was 18 per cent. in one experiment; in another, 60 per cent. more was recovered than was injected, while in nephrectomized rabbits absorption was 47 and 43 per cent. The next series was experimented upon with 1.2 per cent. salt solution, which was injected either immediately after double nephrectomy or about seventeen to forty hours later, and was allowed to remain in the peritoneal cavity for from one-half to six hours. In a number of experiments of this series the average of absorption per kilo. of normal rabbits was one-half per cent., while in nephrectomized rabbits it amounted to 25 per cent. The assumption that there was a rise of osmotic pressure in nephrectomized animals was made more probable by the results of the series with 1.5 per cent. salt solution. In three out of four experiments 10 to 20 per cent. more fluid was recovered than was injected in normal rabbits, while in nephrectomized animals 30 per cent. per kilo. was absorbed. In the next and last series with 2.0 per cent. salt solution, there was a negative absorption, *i. e.* more fluid was recovered than was injected, manifested itself for the first time in nephrectomized rabbits, which was, in all probability, an indication that 2 per cent. salt solution was hyperto ic for nephrectomized rabbits. Experiments with a stay of six hours in the peritoneal cavity did not show any difference between the normal and nephrectomized rabbits in any of the different series that were considered. Thus they obtained similar results with 2.0 per cent., 0.8 per cent., and 1.2 per cent. salt solutions, which is apparently due to the fact, proved by many investigations, that liquids whether hypertonic or hypotonic became isotonic with the blood after a longer stay in the peritoneal cavity. The results showed that the power of absorption was considerably increased in nephrectomized rabbits. This held good for at least twenty-four hours after nephrectomy. In one instance it was found that even after forty-one hours' absorption was better in nephrectomized than in normal animals. In another instance there was no difference. These results would explain the fact that no œdema is seen after nephrectomy in animals. They also explain the clinical observation of anuria persisting for many days without leading to œdema. The cause of all this was that the first effect of nephrectomy was not an increase of transudation of lymph into the tissue spaces, but an increase of absorption from them.

Dr Levene asked whether the investigators had considered that there was only the one possibility that the increase of osmotic pressure in the blood was the cause of the impairment of absorption after nephrectomy, and this was the case, and since the theory was so new, whether there had not been some chance to prove that the osmotic pressure of the blood was really so much higher than in normal animals. It seemed to him that in advancing such a new theory it would be desirable to corroborate it. The technical methods of determining the osmotic pressure in the blood were so simple and easy to carry out that he thought the determination should have been made before such important conclusions were drawn as the result of the experiments.

Dr. Meltzer said that in the first place the experiments were carried out with the idea of demonstrating whether absorption was increased or diminished in nephrectomized animals, and the question of the determination of the osmotic pressure of the blood was an entirely secondary matter. Indeed, these determinations had already been made by Koranyi, and were published in one of his articles, although as the reference was in a foot-note it might easily be overlooked. In fact, Dr. Meltzer and his associate had not known of it until after they had made some of their experiments. Koranyi states that he found a distinct difference in the freezing point of the blood of normal and nephrectomized animals. In normal animal the freezing point was 0.56; in nephrectomized animals, 0.70.

Dr. Levene then asked if the alterations in the circulation, or vasomotor disturbances due to the operative technique, might not have caused the increased absorption.

Dr. Meltzer said there was no hyperæmia of the peritoneum after operation. The incisions were made as small as possible, and the autopsies had shown that there was no peritonitis. Besides, peritonitis did not favor but rather retarded absorption. That there was no especial change in the circulation after nephrectomy was shown long ago by v. Limbeck.

Remarks on Vasomotor Nerves, with Demonstrations.—Dr. S. J. Meltzer read a paper written by Dr. Clara Meltzer and himself on this subject. He said that since 1852 the sympathetic had been considered the sole or main vasomotor nerve of the ear. This was the impression one got from examining textbooks on physiology. They investigated the subject in a series of twenty-one rabbits. Without entering upon a description of the operation, Dr. Meltzer gave the following results: In about one-half of the animals the dilatation of the vessels of the entire ear, after section of the third cervical, was well marked and as good, if not better, than that following section of the sympathetic. In only two section of the cervical had almost no effect. In the balance the dilatation was chiefly in the vessels of the upper part and sides of the ear. Section of the left cervical gave more distinct effects than that of the right. It seemed that this applied also to the sympathetic. In a number of animals they especially noted that while the effect of the section of the sympathetic is considerably diminished in three or four days, that of the cervical continues in most animals undiminished for a much longer period. Dr. Meltzer gained the impression that the color of the animal had some influence. Stimulation of the peripheral cut end of the cervical had also given in many cases a greater constriction than the stimulation of the sympathetic. In some animals the constriction affected the vessels of the entire ear; in others it affected only the vessels of the top and sides; and in a few there was no effect. In all cases both sides were different, the left side usually giving greater effects. A few cases were observed in which stimulation of the cervical had very little or no effect; nevertheless section of this nerve caused considerable congestion of the ear, which showed that the cervical maintained a vasoconstricting tonus. This meant that normal stimuli were more adequate than the artificial ones which we usually employed in experiments. These experiments demonstrated that the blood vessels of the rabbit's ear were under the control of two separate sets of nerves, the cervical and the sympathetic, which could substitute one another—a

striking example of collateral innervation. The authors showed two rabbits which demonstrated some of the phenomena referred to in the paper.

Dr. I. Levin said that he had been interested in Dr. Meltzer's statement that the color of the animals had seemed to have some influence on the results of the experiments. In the work which he had himself done requiring intravenous injections, he had always preferred white rabbits. He asked Dr. Meltzer whether he had also found that the vessels of the white rabbit were more developed and whether that explained why the widening after the cutting of the nerve was greater. He also asked whether there was not a difference between the results of the operation in the right side and on the left side. In nature these arteries, he said, were larger on the right side than on the left. Would not the difference in the normal caliber of the arteries on the two sides interfere with the measurements after cutting of the cervical nerves?

Dr. Meltzer said that in regard to the question of the different results according to the color of the rabbit they did not wish to go on record. Hundreds of rabbits would have to be studied before a conclusion in this regard could be positively demonstrated. With regard to Dr. Levin's second question, Dr. Meltzer said that the difference between the right and left sides in the widening of the vessels after section of the nerves were not a matter of theory but of observation. They had seen the blood vessels before the section of the nerves, and knew that there was no such performed anatomical differences between the two ears. Nor would this have anything to do with the question of stimulation. By stimulating the nerves on the left side a greater effect was produced than by stimulating those on the right side. This fact had nothing to do with the original size of the vessels.

Experiments Relating to the Fixation of Strychnine by Animal Tissues.—Dr. Gustav Langmann read a paper by Dr. S. J. Meltzer and himself on this subject. While it was formerly supposed that strychnine, whether taken by the mouth or injected hypodermically, combined with the tissues, Dragendorff and other observers proved that it left the system unaltered and was principally excreted by the kidneys within less than forty-eight hours. Von Czyhlarz and Donath revived this question in 1900 by claiming that strychnine when injected into a ligated extremity of a guinea-pig was neutralized by contact with the living tissues. Meltzer and Langmann, repeating the same experiments, were unable to confirm these statements; they thought it probable that absorption was impaired by the constriction and that sufficient elimination took place, so that at no time an efficient minimum was reached. Carrara, however, sustained the theory of v. Czyhlarz and Donath by apparently conclusive experiments. After checking all elimination through double nephrectomy he found that strychnine injected into a ligated extremity caused no symptoms. Although this premise sounded very plausible, it had never been tested by experiment, and Meltzer and Salant found that rabbits, at least after double nephrectomy, would tolerate the gradual injection of the triple lethal dose without exhibiting the least effect of strychnine. The same experiments were repeated by Meltzer and Langmann on guinea-pigs, and it was found again that after double nephrectomy doses far above the lethal could be injected without obtaining a single symptom of strychnine poisoning, provided that not too large doses were used, and that they did not follow each other too closely. The gradual injection of as much as 20 mgr. per kilo did not even cause a hyperæsthesia, although the lethal dose for normal animals is 4 mgr. per kilo. These experiments, therefore, could not be adduced to sustain von Czyhlarz and Donath's theory. It was furthermore established that strychnine was ineffective only provided it was not injected within the first three hours after nephrectomy. Previous to that period even subminimal doses proved fatal. Some of the nephrectomized animals exhibited a subtetanic reaction, a peculiar continuous vibration, ending in death within an hour. It seemed likely that during the hours following nephrectomy the system elaborated a compensatory mechanism of elimination for the injection of strychnine into a ligated extremity proved to be fatal if nephrectomy was performed and the ligature loosened three hours after the injection.

Dr. P. A. Levene said that he had made the same observations that Dr. Langmann had made in support of his theory as to the reaction of the organisms on strychnine. He said that a paper had appeared during the year on the antitoxic effect of nerve tissue on tetanus toxin. It was claimed by the author that nerve tissue had not the power to absolutely neutralize tetanus toxin, but to a certain extent diminished its effect. Tetanus toxin was given to an animal mixed with the pulp of brain tissue. It was found that smaller amounts of antitoxin were needed to save the life of the animal than when the toxin was injected directly without the brain emulsion. The author, therefore, claimed a specific antitoxic effect for the brain emulsion. It seemed to Dr. Levene that a simpler explanation would be that the tetanus toxin acted more slowly in the colloidal solution than when injected directly, and that, therefore, less antitoxin was necessary to save the life of the animal.

Dr. Meltzer said that he arose again not to defend his own experiments but those of another. Wassermann's experiments were not performed by mixing brain tissue and tetanus toxin, but the toxin was injected into one side of the animal and the brain tissue into the other side.

Dr. Levene then said that he had not had reference to Wassermann's experiments.

Books Received.

Diseases of the Eye. By G. E. De Schweinitz, M.D. Fourth edition. 8vo, 773 pages. Illustrated. W. B. Saunders & Co., Philadelphia, Pa. Price, cloth, $5.00 net; sheep or half morocco, $6.00 net.

Twentieth Century Practice of Medicine. Edited by Thomas L. Stedman, M.D. Vol. XXI. Royal octavo, 845 pages. Illustrated. William Wood & Co., New York. Price, $5.00.

A Manual of Materia Medica and Pharmacology. By David M. R. Culbreth, M.D. Third edition, octavo, 916 pages. Illustrated. Lea Brothers & Co., New York.

Anatomy. By Wm. H. Rockwell, M.D. 8vo, 520 pages. Illustrated. Lea Brothers & Co., New York.

Progressive Medicine. Vol. IV. By Hobart Amory Hare, M.D. 8vo, 422 pages. Illustrated. Lea Brothers & Co., New York City.

The Practical Medicine Series of Year Books. Vol. II. General Surgery. By John B. Murphy, M.D. 12mo., 553 pages. Illustrated. The Year Book Publishers, Chicago, Ill. Price, $2.00.

Therapeutics of Dry Hot Air. By Clarence Edward Skinner, M.D. 8vo., 200 pages. Illustrated. A. L. Chatterton & Co., New York. Price, cloth, $2.00.

Biographic Clinics, the Origin of the Ill-health of DeQuincy, Carlyle, Darwin, Huxley, and Browning. By George M. Gould, M.D. 8vo, 223 pages. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $1.00 net.

Historia De La Medicina En Guatemala. By Francisco Asturias. 8vo, 557 pages. Illustrated.

Transactions of the Twenty-fourth Annual Meeting of the American Laryngological Association. 8vo, 259 pages. Illustrated. Rooney & Otten, New York.

Book on the Physician Himself, His Reputation and Success. By D. W. Cathell, M.D. 8vo, 411 pages. The Twentieth Century Edition. F. A. Davis Co., Philadelphia. Price, cloth, $2.00 net.

Tratado Teórico-Práctico de las Enfermedades de los Niños. By Doctor Francisco Criado y Aguilar. Imprenta del Asilo de Huérfanos del S. C. de Jesús, Madrid. 25 pesetas.

Estudio de un Sistema de Alcantarillado para Málaga. By Don Ramón Martín Gil. Vinda de J. Hiral, Malaga.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 31, 1903:

	Cases.	Deaths.
Measles	164	8
Diphtheria and croup	361	60
Scarlet fever	264	15
Smallpox	3	1
Varicella	129	..
Tuberculosis	248	163
Typhoid fever	34	9
Cerebrospinal meningitis	..	..

The Prophylactic Treatment of Typhoid Fever by Inoculation.—W. C. Stevenson reviews our knowledge on typhoid prevention in the manner described, and says that out of seventy cases only one patient was compelled to go to bed. This patient had a mild fever for twenty-four hours. Another patient vomited three hours after inoculation. The symptoms were mostly local. Two hours after injection the muscles in the region of the wound were stiff and painful on movement. This sensation was at its height the following morning, and subsided slightly during the day, having disappeared entirely by the morning of the fourth day. On the second inoculation local symptoms were but little marked, but there was slight malaise for a day or two. The immunity brought about seems to be similar, but more certain than that produced by long residence in a locality in which typhoid fever is endemic. Inoculation does not absolutely prevent the disease, but statistics incontestably show that the percentage of cases among the inoculated is considerably less than among those not thus treated, the exposure in both classes being the same. The caution is given that discretion must be exercised in practising inoculation in the presence of an epidemic, when an overdose of the typhoid vaccine would for a short period lower the resisting power of the disease. —*Dublin Journal of Medical Science.*

An Old Plan of Treatment for Acute Coryza.—Sternberg describes a method of treating this annoying condition, which is based on the long forgotten plan of an eminent teacher of a former generation, M. J. B. Williams. This consists in abstinence from fluids during the early stage of the disease, whereby the natural secretions of the body use up the reserve fluid present, and the excessive secretion of the affected mucous membranes is checked. The local irritation is thereby also lessened, and the return to the normal state greatly hastened. The treatment must be begun with the first symptoms of the malady, and continued for forty-eight hours in ordinary cases and longer for obstinate ones. The diet should be light and easily digestible, and all soups, beverages, etc., omitted. A teaspoonful of tea or coffee at breakfast and a wineglassful of water at bedtime do not impair the efficacy of the cure. The great advantage of the method is the fact that it can be carried out by anyone and does not in any way interfere with ordinary duties of life, so that even those who ordinarily consider a "cold" as a necessary evil too trifling to justify any confinement to the house or other restrictions can easily carry out this plan.—*Zeitschrift für Diätetische und Physikalische Therapie.*

The Technique of Gastric Lavage.—C. Neck says that the usual procedure of siphonage suffices to empty the stomach to a satisfactory degree in most instances. In cases of motor insufficiency, however, a certain amount of fluid always remains behind, while in surgical operations on the stomach it is especially important that the organ be completely empty before it is incised. In such cases after the lavage has been kept up in the ordinary way until the washings return clear the patient is placed in the Trendelenburg position. A further quantity will immediately be discharged, and as the tube is slowly withdrawn, the flow will continue until the instrument has left the cardiac orifice, when the organ will have been entirely emptied. Experiments on the cadaver showed that when the operation was performed in the ordinary way, a little pool was always left behind, but on the change of position, this gravitated to the cardiac, and could then be aspirated if the tip of the tube were kept in the fluid by slowly pulling it out at the mouth.—*Centralblatt für Chirurgie.*

Causes of Death.—The fifteen principal causes of death, with the rate per 100,000, as made public by the census bureau, is as follows: Pneumonia, 191.9; consumption, 191.5; heart disease, 134; diarrhœal diseases, 85.1; kidney diseases, 88.7; apoplexy, 66.6; cancer, 60; old age, 54; bronchitis, 48.3; cholera infantum, 47.8; debility, 45.5; inflammation of brain and meninge, 41.8; diphtheria, 34.4; typhoid, 33.8; and premature birth, 33.7. Death from all principal causes shows a decrease since 1890, the most notable being consumption, which shows a decrease of 54.9 per 100,000.—*Dietetic and Hygienic Gazette.*

Portal Congestion.—Hemorrhage from secondary ulceration of the stomach, in cases of heart or liver disease, calls for a special line of treatment. Samuel and Sultan Fenwick recommend that the portal congestion be relieved by half a dozen leeches, applied over the liver, while the bowels are freely moved by a mercurial followed by a saline.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending January 31, 1903:

A RÉSUMÉ OF SOME RECENT RESEARCHES RELATING TO CYTOLYSIS AND IMMUNITY.*

BY T. MITCHELL PRUDDEN, M.D.,
NEW YORK.

IN the early years of the new bacteriological era it was chiefly upon the invasive agents in infectious diseases that attention was centered. The characters, sources, variations, portals of entry to the body, and fate of the bacteria—these were the dominant aspects of infection, full of fresh and dramatic interest. To-day the tide is setting toward the nature and variations of the responses of the cells of the host under such new and often baleful conditions as infection involves. It is only now that light from both sides is falling upon the questions which relate to infection and immunity that these are taking their places among related problems of general biology.

I shall not burden you with classification, but it is convenient, for the sake of getting associated facts together to consider immunity to the infectious diseases as either natural or acquired.

The absolute or relative insusceptibility of turtles and fishes for tetanus, of rats for anthrax, and of the lower animals for syphilis and for scarlatina, are examples of natural immunity which we need not further consider here.

Acquired immunity may be the result of a successfully weathered infectious disease, as in the case of smallpox. Or it may be experimentally secured through the gradual adaptation of the body to infectious or to toxic substances without the natural manifestations of infection or intoxication.

There are many ways in which immunity by gradual adaptation may be obtained. For example, by the introduction into the body in increasing quantities or potency of living microorganisms whose virulence has been at first diminished. This reduction in virulence may be secured in various ways; for example, through the action of heat or chemicals; by drying in the air, as in the preventive inoculations in hydrophobia; by the passage through a naturally insusceptible animal, as in vaccinia. Or, on the other hand, immunity by gradual adaptation can be secured by the introduction of the dead bodies of infective microorganisms, or of various toxic substances in increasing doses. But all these methods belong to current knowledge and need not be further dwelt upon.

We can all readily recall the time, little more than a decade ago, when the conceptions of the nature of immunity from infectious disease, whether it were natural or acquired, were most vague and unsatisfactory. Clinical lore relating to the subject was positive; the nature of the infectious diseases in the light of the new knowledge of microorganisms was rapidly assuming definite proportions, and the varied lines of research upon animals were converging more and more upon the conditions under which acquired immunity occurs. But still the heart of the matter eluded our grasp.

Bacteria and other microorganisms are in some way destroyed within the body; this was evident; the body cells do, in some fashion, acquire a capacity to resist the deleterious agencies which are evoked in infection. But the nature of these conservative processes was not clear.

Various hypotheses were framed. Nutrient material in the body becomes exhausted, said one, so that the microorganisms presently die. Self-engendered poisons, said another, lead to their destruction. The results of the brilliant studies of Metschnikoff were formulated in the doctrine of phagocytosis. A long series of observations on the germicidal power of the body fluids led many to adopt the humoral conception of the protective agencies.

But now a new and, in spite of the varied lore which had gathered about immunity, a quite unexpected phase of the subject suddenly developed.

It is not easy to realize with entire clearness to-day the feeling of incredulity with which we faced the announcement—now somewhat more than a decade ago—of the antitoxic capacity of the blood serum of animals which had been artificially immunized against diphtheria toxin. This capacity seemed all the more striking because the serum of the immune animals containing this new stuff, on being transferred bodily to fresh individuals, even though of different species or race, still carried the power to avert the specific toxic effects through which it had been itself evoked. The protection thus secured was not against typhoid fever, or tetanus, or smallpox, but only against diphtheria.

It seemed fairly incredible that the body cells should be able to respond to so peculiar and specific a poison as that of the diphtheria bacillus by the elaboration of a new substance so definitely specific and so definitely conservative. How were we to conceive of what seemed to be new physiological capacities called into being within a few weeks under the influence of agencies brought to bear upon the animal body now, apparently, for the first time in its individual or even in its whole racial history. This seemed teleology in its most striking form, and the cells of the body colony seemed to be fairly raised to the plane of sentient beings, suddenly purposeful and potent for the welfare of the organism.

It all seemed romance rather than science. But diphtheria antitoxin is a real thing. We make it, through the good offices of the horse, in adequate quantities; we test its strength; we bottle and label and inject it. While the chemist cannot isolate it nor write its formula, he tells us that it most resembles the globulins, and its practical value is established beyond the need of proof or rehearsal.

The effect of antitoxin in the blood is not to kill or destroy bacteria, but to render harmless the corresponding toxin. But how is this effect produced? Does the antitoxin destroy the toxin? Apparently not, for after the so-called neutralization of the toxin the latter can in some instances be recovered. It was assumed that the effect is secured by some

*Read before the Practitioners' Society, January 2, 1903.

rapid action of the antitoxin upon the body cells, by which these become speedily invulnerable or are stimulated to produce new substances. But analogous effects can be secured in test-tubes, and here the action of living cells is excluded. Altogether, the facts point toward a chemical union of toxin with antitoxin, whereby the former is deprived of its capacity to injure cells.

This form of antitoxic immunity, secured by the conveyance of the blood serum of an animal gradually adapted to a toxic or infective agent, and containing the protective substance ready formed, is called *passive immunity*, in distinction to the insusceptibility secured by an individual for himself through a direct adaptation to the deleterious substances, which is called *active immunity*.

In active immunity the protective stuff is elaborated by the directly immunized individual; in passive immunity it is furnished ready made. The induction of active immunity takes time; passive immunity is secured at once. Active immunity is usually of considerable duration; passive immunity is evanescent.

Results similar to those obtained in the study of diphtheria antitoxin were soon realized in the investigations of tetanus. But the practical value of the tetanus antitoxin as a therapeutic agent was less obvious. Presently it was shown that antitoxic sera may be developed in the body during immunization to snake venom, vegetable poisons, such as ricin, and to other albuminous animal and vegetable materials. Thus, also, through experimental adaptation, the living body cells may elaborate and set free into the serum substances which suspend the action of ferments like rennet, pancreatin, fibrin ferment, etc.

Now, for a time, the possibilities of serum therapy seemed boundless, and the preparation of sera against all sorts of pathogenic bacteria went on at a breathless rate. Pneumonia and typhoid, streptococcus septicæmia and plague, tuberculosis, and cholera—these and many other sera have been faithfully and persistently studied. But one after another they have been found to be, for the most part, of doubtful value and have been set aside. The analogy of other infections with diphtheria and tetanus seemed to be somehow faulty, and the key to the difficulty was wanting.

The nature of the immunizing process was still so obscure and the failures, except with diphtheria and tetanus, were so conspicuous, that Virchow, a little jealous always of the bacteria which had for the moment crowded his beloved cells aside, was not without justification in his assertion that with all the talk of serum therapy we had obtained, indeed, in single instances, empirical practical results, comparable with Jenner's vaccination, but offering no more than did his discovery any theoretical insight into the nature of the processes through which the effects were secured.

Just at this period, then, the condition of affairs, as regards artificial immunization in man, was about as follows: There were two practical methods in vogue, vaccination for smallpox, and preventive inoculation in hydrophobia; both elaborated in entire ignorance of the inciting microorganism, and both highly successful. There was then the method by antitoxic serum of the greatest practical value in diphtheria, of much less certain usefulness in tetanus. This serum method of so-called passive immunization was developed as the result of the most painstaking researches on the bacilli known to be the incitants of these diseases, and leading, step by step, to one of the most noteworthy triumphs of modern science.

But so far as man was concerned the protective sera for a long list of other infectious diseases, which had been widely tested, had been so uniformly unsuccessful as to lead to the conjecture that, while there is a form of immunity which can be appropriately designated as antitoxic, in the greater proportion of immunizations other protective agencies must be at work which were still but incompletely accounted for in the doctrine of phagocytosis or in the current conceptions of humoral germicides.

A good deal of lore had been gathered about the germicidal action of blood serum and certain of the phagocytic body cells under various conditions. But the nature and details of the process by which bacteria are destroyed in the body remained obscure.

Several years ago, however, Pfeiffer showed that the peritoneal fluid of a guinea-pig, artificially immunized against the cholera vibrio, was capable, under certain conditions of not only immobilizing and killing in a short time cholera germs placed in the peritoneal cavity of the living animal, but also of causing their disintegration and destruction. This significant capacity of immune serum was, after a long series of experiments, finally found to be due to two distinct substances. One of these appeared to be formed in the body, as the result of the gradual adaptation of the animal to the cholera microbe, and was called the *immune substance*. The other seemed to be normally present in the serum of the warm-blooded animals, and to be identical with the substance which had long been regarded as in itself germicidal, and which had been called by Buechner *alexin*. It was presently found that lysis of the cholera microbe occurred only when these two substances act together, neither of them when separate having lytic power. If the two substances, the immune substance and the alexin, lytic when together, were heated to 70° C., the lytic capacity was lost. But if a small amount of fresh blood serum containing alexin were now added, the lytic power was at once restored. These curious facts, set forth in part by Pfeiffer and further developed by Bordet and Metschnikoff, obviously have an important bearing upon our conception of the processes by which some phases of immunity are secured.

But the study of the effects of lytic sera upon bacteria is one of great technical difficulty, owing to the minute size of the organisms and the conditions under which they can be observed. So the advance of knowledge in this direction halted for a time, and the observations of Pfeiffer did not at once assume their full significance.

It was evident, however, that two phases of immunity should be recognized, *antitoxic immunity* and *bacteriolytic immunity;* though it was not then, nor is it yet, clear whether these may not frequently or always be associated in the protective processes.

The "Side-Chain" Hypothesis of Ehrlich.—Just here, before passing to some recent researches bearing upon bacteriolytic immunity, I should like to recall to your memory the so-called "side chain" hypothesis of Ehrlich, by which he strove to account for the phenomena of antitoxic immunity as exemplified with especial clearness in diphtheria and tetanus. Without this hypothesis we are to-day still practically at sea and adrift in our views of the nature of antitoxic immunity. While this remarkable capacity of the body to manufacture off-hand the greatest variety of potent specific antidotes to the most subtle and virulent poisons becomes, for the first time, comprehensible in the light of this ingenious conception. It is now several years since Ehrlich's hypothesis was enunciated, and whatever may be its merit as a direct contribution to science,

there can be no doubt that it has been, in a remarkable degree, an inspiration to the most fruitful research. It is practically impossible to follow the recent work on immunity without a knowledge of this hypothesis and familiarity with the nomenclature to which it has given rise, and I, therefore, ask your attention to a brief review of its more important features.

In order fully to comprehend the hypothesis of Ehrlich regarding the origin and nature of antitoxin, it is necessary for us to form with him a clear conception of cell assimilation.

We conceive of the cell as a mechanism for the storage of energy derived from without and for its release under definite conditions. This storage of energy is possible through the assimilation and building up by the cell of complex molecular combinations. These, owing to their instability, are readily resolved into less complex and more stable combinations with the release of the stored-up energy. Thus is the life of the cell manifested.

This broad conception of the cell is a purely intellectual one, however, for the details of cell metabolism still elude the keenest scrutiny of the chemist. He cannot formulate protoplasm nor express its chemical changes proportionate symbols.

Now, accepting this condition of affairs as for the moment inevitable, Ehrlich seeks to express his view of the character of the cell's performances in general terms, disregarding its morphological peculiarities, somewhat as follows: We may conceive of the cell as consisting of a central group of very complex molecular combinations which maintains the characteristics and special capacities of the cell as an organism under all the vicissitudes of its existence. Associated with this central organic group are many and varied subsidiary atom-complexes which by means of their unsatisfied affinities bring the central group into relationship with food material through those chemical combinations which in living protoplasm characterize assimilation.

These unsatisfied affinities by which assimilable material is fixed or united to the cell have been called "side chains," a term adopted from the chemist. Not to press too closely, however, the analogy between the chemical processes in lifeless substances and assimilation in living matter, these affinities or "side chains" of protoplasm are now commonly called *receptors*.

If we seek to illustrate Ehrlich's conception we shall be obliged to use graphic figures of extreme

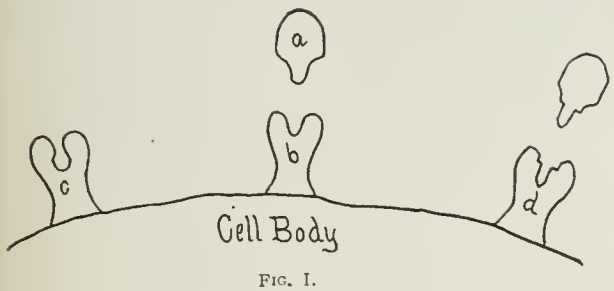

Fig. I.

crudity. If the arc of a circle in Figure I represent a portion of the periphery of a cell, we may indicate the side chains or affinities or receptors by projections whose special shape shall indicate their special capacity to combine with any substance coming in contact with them under favorable conditions. Suppose in this figure we let *a* represent a nutrient molecule which is capable of combining with the receptor *b*. Through its union with *b*, and only through this, is it capable of entering into the metabolism of the cell. This molecule *a* cannot unite with the receptor *c* or *d*, but only with such receptors—to use the crude expression which our illustration requires—as it fits. Through the receptors *c* and *d* other forms of food molecules may enter into the metabolism of the cell.

Thus it is in Ehrlich's conception, which after all is only a graphic way of illustrating the preliminary phases of assimilation by living protoplasm, that the cell is capable of selecting or "fixing" out of the host of various substances with which it comes in contact, just those and only those to which its receptors bear a definite chemical relationship.

The same thing is true of toxic as of nutrient substances. In order to be toxic to the cell they must enter into chemical combination with a suitable receptor of the cell. Then only can they lead to the forms of damage which we are here considering.*

As the result of many studies on the nature and effects of toxins, Ehrlich is led to believe that the toxin molecule consists of two forms of affinities; one through which the chemical union with the cell is effected—called the haptophorus group; and the other—called the toxophorous group—by which the damage to the cell is brought about when once the toxin molecule is anchored to it.

This conception may be illustrated as in Figure II, in which the toxophorous group *a* of the toxin

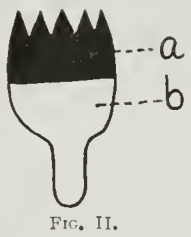

Fig. II.

molecule can be effective in damaging the cell only when united to the latter by the haptophorous group *b*. Ehrlich was led to this belief in the complex nature of the toxin molecule through the very curious fact that diphtheria toxin may under a variety of conditions lose its toxicity but still retain its capacity of neutralizing antitoxin and also of uniting with cells, and thus inducing the formation of antitoxin in the animal body. Such toxin molecules deprived of the toxophorous group are called *toxoids*.

Having now with Ehrlich conceived of the living cell as consisting of a central essential complex molecular group, brought into relationship with its food materials by means of a great number of the most varied receptors, through which, under normal conditions, assimilation is secured, let us see what may happen if toxins come in contact with living cells which are furnished with receptors capable of uniting with them.

The union of the toxin molecule with the living cell being effected, the cell is more or less damaged. If the damage be sufficient, the cell dies, and that is the end of it so far as our present inquiry is concerned. But suppose the damage to be but slight, as may be the case in artificial immunization or in early stages of an infection. The cell is at least deprived of the useful offices of the receptor to

*It is evident from what has been said about the conditions under which substances can be toxic that the immunity of one animal to a given agent which is toxic in another may be simply due to the fact that the cells of the former have no receptors with which this agent can unite, or if this union does take place that the cell is not thereby damaged. This consideration has an important bearing upon our conception of natural immunity.

which the toxin molecule is now united. This is in itself a loss to the cell, and through the regenerative impulses common to all living cells it proceeds to regenerate the lost parts, which in this case are the receptors. But as more receptors are thrown out of function by the continued action of the toxin, the necessity for compensation continues.

Now it is a fact long known to pathologists, and especially emphasized by Weigert, that the regenerative impulse is apt to be in excess of the obvious requirements and leads to overproduction of new cells, tissues, chemical substances, etc. Just this is what now happens to the cells, some of whose receptors have been rendered useless by combination with the toxin. New receptors are formed, more than the cell requires; so numerous may these become that many are at last cast off into the blood. Now here is the point at last. *These receptors or substances, normal and useful to the body, but now formed in excess through over-compensation, and set free from the cells into the body fluids, are the antitoxin.*

For, cast off into the body fluids, these superfluous receptors still retain their combining power for the free toxin molecules, which, also, are floating in the body fluids, and unite with them. This union having been effected, the toxin molecules are no longer a menace to the cell, because the affinities are now satisfied through which they joined the receptors while these were still a part of the cell, and in this way became harmful. This now inert combination of toxin molecules and detached receptors is physiologically indifferent stuff, and may be got out of the body through the usual processes of excretion.

But the antitoxin which has not united with toxin in the body of the animal which produced it is still available on the transferrence of the serum to another individual whose blood contains diphtheria toxin, and who may thus secure passive immunity.

If we have recourse again to our graphic efforts, the hyperproduction of receptors by the damaged cell, their separation, and their action as antitoxin, may be indicated, as in Figure III. The toxic mole-

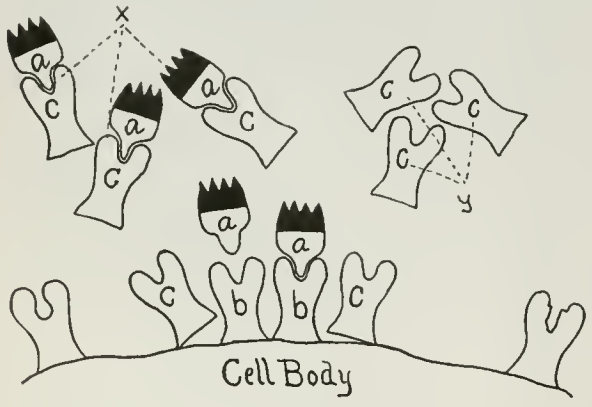

Fig. III.

cules *a*, uniting with the receptors *b*, lead through the injury to the cell, as well as by its deprivation of the normal use of *b*, to the production, and at length to the overproduction of new receptors of the same kind. These superfluous receptors *c* are now cast off into the body fluids,* where, as at *x*, they may freely unite with the floating toxin molecules, forming harmless compounds and preventing further access to the cell, where alone the damage can be done. Or when free, as at *y*, the receptors may be transferred in the serum, becoming effective as antitoxin in another individual.

It is well to note that so long as the receptor maintains its connection with the cell it is not antitoxin, but an element of vulnerability to the cell. It is only when the receptor has been set free from the cell that it is antitoxin.

The antitoxic substance which neutralizes the action of the toxin molecule of diphtheria is not effective for the poison of tetanus, for example, simply because it does not combine with the molecule of tetanus toxin. It *is* specific for diphtheria, because it was the diphtheria toxin which excited its overproduction through a chemical union identical in character, whether this union takes place while the receptor is a part of the cell, in which case the toxin becomes harmful, or when the receptor is detached from the cell, in which case the combination is harmless.

In the light of this hypothesis the incredible becomes the inevitable. The specific character of the antitoxic substances, so mysterious as to seem at first fairly to transcend physiology, is, in fact, but the result of adaptation to unusual conditions of cell capacities evolved and fostered for the every-day maintenance of life. The specific relationship between the toxin and the antitoxin is not developed during immunization, but existed beforehand as a necessary condition of toxic action.

We can account by this hypothesis not only for the formation, protective action, and specificity of antitoxin, but we see, also, a special significance in the incubation period, during which the conservative forces are mustering. We can realize, furthermore, in the light of this hypothesis, how it is that the protection secured in active immunization is less immediate and also why it is more prolonged than in the passive, since in the latter the available antitoxin is limited to the dosage and is not replenished as in active immunity by the continued cell activities of the affected individual himself.

The conception of Ehrlich as to the nature of antitoxin is that of the chemist, and carries over to the performances of protoplasm the presumptions upon which chemical reactions in general are conceived and formulated. But this is not an easy matter, since our knowledge of the ultimate phases of protoplasmic metabolism is very incomplete. The physiological chemist presents to us as his final achievement in analysis an extremely elaborate complex which he calls the proteid molecule. This he does not yet venture to formulate. Its obvious importance and versatility he can indicate, but cannot yet follow with precision. Thus it is that when we attempt to illustrate in graphic fashion our conception of the performances of proteid molecules, either in normal metabolism or in poisoning, we are forced to use the crudest of symbols and to indicate the affinities or combining predilections of our molecular groups by forms which are more suggestive of the carpenter or of the locksmith than of the subtle forces which dominate this under-world of life. The use of such pictures is not without hazard, for these toxins and these receptors are in truth not histological structures, but molecular groups; they are not alone upon the surfaces but through all the mass of the protoplasm. And if one cannot at last translate these uncouth symbols into the nice conceptions of the chemist they will prove but stumbling blocks and may lead to his speedy undoing.

There has been much discussion of Ehrlich's hypothesis, and it has withstood many assaults, mostly inspired by misconceptions of the fundamental claims. The scope of this paper does not

*These receptors of various kinds, cast off into the body fluids under the most diverse conditions, Ehrlich has called "haptines."

permit me to touch upon the many and most ingenious experiments by which this view of antitoxic immunity has been sustained, nor is it practicable now to call attention to many of the phenomena not yet accounted for or seemingly inconsistent with the interpretations here set forth.

Having thus glanced at antitoxic immunity, let us now turn to a new line of research bearing upon bacteriolytic immunity which has already led to most significant results and opened biological fields of great scope and complexity.

Cytolysis.—It has been known for some time that the blood serum of one animal species, when injected into the vessels of another may do serious damage, and even kill the latter through a rapid separation of the hæmoglobin from the red blood-corpuscles. This dangerous effect brought to a speedy end attempts which were at one time made to sustain the ebbing forces of life by the transfusion of alien blood. But the significance of this so-called "laking" of the blood by mixture with alien sera was overlooked and passed into the textbooks on physiology as another of the many curious and unexplained phenomena relating to red blood cells.

Bordet, however, was led to inquire whether if the animal body be capable of adapting itself to toxic substances and to bacteria in such a way as to neutralize the effects of toxins and to destroy bacteria, as had been shown by earlier experiments, it may not respond similarly to the introduction of other foreign substances, such as alien red blood cells, for example.

The blood serum of the guinea-pig is not normally lytic for the red blood cells of the rabbit; that is, it does not cause the separation of the hæmoglobin from the stromata, with a partial destruction of the latter. Now Bordet injected a few cubic centimeters of the whipped blood of the rabbit, containing the serum and red blood cells, into the subcutaneous tissue or peritoneal cavity of normal guinea-pigs. This operation, which does not markedly interfere with the well-being of guinea-pigs, was repeated five or six times with intervals of a few days. When now blood was drawn from the treated pig, allowed to clot, and the clear serum secured, it was found to have become markedly lytic for rabbit corpuscles. A very small proportion, mixed with rabbit's blood diluted with physiological salt solution, in a short time brought the hæmoglobin into a clear ruby solution in which the stromata or "ghosts" of the corpuscles floated as a pale and scarcely visible cloud. This process is called *hæmolysis;* serum possessing this capacity is called *hæmolytic* or *hæmotoxic* serum.

This adaptation of one animal to the red blood cells of another species may be accomplished without difficulty with a great variety of animals.

But a most remarkable thing about this newly acquired lytic capacity of the serum is that it is limited to the red corpuscles of the species of animal whose blood was used for the injection—in Bordet's experiment to the corpuscles of the rabbit. Red blood cells of the dog, cat, sheep, bovines, fowl, etc., are no more affected by this serum of a guinea-pig which has been adapted to the blood of the rabbit than they were before. In other words, the adaptation to foreign corpuscles is specific.

I have said that this adaptation to alien blood is specific; that is to say, the serum becomes active only for the corpuscles of the species injected. This statement should, however, be so qualified as to recognize the curious fact that a slight degree of lysis may often be induced in corpuscles of species of animals very closely related to those from which the injected blood is derived. For example, if a rabbit be adapted to human blood by intraperitoneal injections, the serum of this rabbit, now strongly lytic for the corpuscles of man, may be slightly lytic for the corpuscles of monkeys. Similarly, serum artificially lytic for the red cells of goats may be slightly lytic for those of sheep, but not for the corpuscles of cats, dogs, man, etc.

This form of test, delicate beyond anything hitherto known in physiological chemistry, may thus prove of value in defining the relationships and limitations of animal species.

I show to you here, in illustration of this remarkable experiment, a series of slender test tubes placed against a white background. In this instance the material which I show was secured by adapting the rabbit through successive intraperitoneal injections to beef blood. In the first tube is a little simple salt solution of a strength of 0.85 per cent., which is approximately isotonic for red blood cells. To this salt solution I have added a small quantity of beef red blood cells. You see that the corpuscles have settled to the bottom leaving the perfectly colorless salt solution above. In the second tube is the same quantity of beef corpuscles which have been mixed with normal rabbit serum. Here also the corpuscles have settled to the bottom, leaving the clear, color less serum above. You see from these two control experiments that neither physiological salt solution nor normal rabbit serum are lytic for beef red blood cells.

The third tube is prepared in the same way as number two, except that here the fluid is serum from a rabbit which has been adapted by successive intraperitoneal injections to the beef corpuscles. Here the corpuscles have disappeared save for a faint cloud at the bottom composed of the colorless "ghosts" of the cells, while the fluid has the fine ruby color of dissolved hæmoglobin. This adapted rabbit serum is therefore hæmolytic for the beef corpuscles.

In order to show to you the specific character of this adaptation I have here two tubes containing the serum of the beef-rabbit, to one of which I have added corpuscles of the dog, to the other corpuscles of man. In these there is no solution of the hæmoglobin; the corpuscles lie in a red mass at the bottom; the serum above is colorless.

This preliminary observation of Bordet was immediately followed by a series of studies upon artificial hæmolysis, the results of which I shall summarize in the simplest fashion. In the first place, to what is this remarkable acquired lytic capacity of the serum due? Bordet heated for half an hour to 56° C. some of the lytic serum secured by adapting the guinea-pig through subcutaneous injections to the red blood cells of the rabbit. He found that it had completely lost its new lytic power. But when he now added to this inert serum a little fresh blood serum from a normal guinea-pig, which is not in itself lytic, the original dissolving power of the heated serum for rabbit corpuscles was at once restored. The inference from this experiment is obvious. The dissolving capacity of this artificially lytic serum is due to two distinct substances. One of these, that one which results from the adaptation of the animal to the alien blood, is stable at 56° C.; the other, which is present in normal serum, is rendered inert at 56° C.; that is, it is very labile. These two substances were named early and have been often renamed. For the present I shall speak of the stable substance resulting from the adaptation to the alien blood as the "*immune substance*" or "*immune body*," and of the other, more sensitive to heat and present in normal serum, as "*alexin*," a name which was long

ago applied by Buchner to a substance or substances in normal serum, to which its germicidal capacity, first clearly demonstrated by Nuttall, was attributed.

Here is a series of tubes illustrating these points. In this first tube is a little normal rabbit serum which has been mixed with beef red blood cells. The cells have settled to the bottom, leaving the colorless serum above. In the second tube is the serum of a rabbit which has received a series of intraperitoneal injections of beef blood to which I have added the same quantity of beef red blood cells as in tube 1. But these cells have disappeared and the serum is red with dissolved hæmoglobin. This adapted serum is thus lytic. In tube 3 are the same substances as in 2, except that the beef-rabbit serum, seen to be strongly lytic in No. 2, has been heated for one-half hour to 56° C. Here you see there is no lysis of the corpuscles. They lie unchanged at the bottom of the tube. The fluid above is colorless. In tube 4 I have the same substances as in tube 3; namely, beef corpuscles and heated beef-rabbit serum (not in itself lytic) but I have added a very little fresh normal rabbit serum which, as you may see from the control tube 1, is not in itself lytic. It does, however, contain alexin, and you see that it has "reactivated" the heated serum of tube 4, so that complete hæmolysis has occurred.

There now followed a series of important studies by Ehrlich and his associates which throw still further light upon these curious lytic agents.

We have seen that in order to secure the immune substance free from the alexin one has only to heat the lytic serum to 56° C., for half an hour, when the alexin is destroyed. If one wishes to secure the alexin apart from the immune substance he makes use of a very curious property of the latter; namely, its capacity of uniting with the cellular element under whose influence it was elaborated. For example, if one places a small portion of the serum of a rabbit which has been adapted to beef blood in contact with beef corpuscles at a low temperature* for a few hours, he will find that the immune substance has formed so staple a combination with the corpuscles that on their separation from the fluid by centrifugation, none of the immune substance, but all of the alexin, will be left in the fluid.

That the corpuscles under these conditions actually contain the immune substance is readily shown by adding to them a little normal serum—containing alexin but no immune substance—whereupon the lysis will at once take place, as shown by the red color of the fluid. This union of the immune substance with corpuscles is strictly specific, occurring only with the corpuscles of the animal species used in the adaptation.

Many other points of extreme interest and significance have been revealed in these studies on artificial hæmolysis which I have not time to touch upon.

The question of a multiplicity of immune substances and of alexins has been brought forward, and it seems probable, especially from the researches of Ehrlich, that in adaptation of each animal species to a single form of cell several immune bodies may be developed. It is not unlikely, furthermore, that more than one alexin may be normally present in the blood serum of each animal species, and that a single immune body may be capable of uniting with several forms of alexin.

It has been found that the hæmolytic capacity of the *normal* blood serum, which in many animals, as we have seen, is very marked for the corpuscles of alien blood, is also due to two substances which in character and action are similar to those which have been so carefully studied in the lytic sera of artificially adapted animals.

It is evident that this artificial hæmolysis, secured by the adaptation of one species of animal to the red blood cells of another, is quite analogous to the process by which immunity is secured against pathogenic bacteria—cholera, for example—and which is called bacteriolysis. Both are specific examples of the general process called cytolysis, meaning cell destruction. But this reaction of hæmolysis is not only one of extraordinary delicacy, but is easily observed under conditions quite within our control, and permitting such elaborations and variations as involve great technical difficulties when we are directly engaged with the phenomena of bacteriolysis.

Thus these studies of hæmolysis have a practical significance in their bearing upon our conceptions of bacteriolytic immunity quite apart from the interesting general biological field into which they have led the way.

The development of cytolytic capacities in the blood serum of the living animal as the result of adaptation to bacteria and to alien red blood cells being known, it was natural to extend the method to other cells.

Thus it has been found that in the adaptation of one animal to the spermatozoa of another species by intraperitoneal injections, a serum is obtained which quickly brings to an end the movements of fresh spermatozoa of the species used—*spermotoxic* serum.

Similarly, specific *leucolytic* sera have been procured by intraperitoneal injections of emulsions of lymph nodes, spleen and bone marrow. Such leucolytic sera may not only dissolve the leucocytes outside of the body, but they are extremely toxic when introduced into the living species from which the tissues originated. The effects of these leucolytic—leucotoxic—sera in the body are most pronounced in the blood-forming organs. Here, as the studies of Flexner show, a very significant impulse to new cell formation may be associated with the action of the leucotoxic sera.

Emulsions of liver cells of one species injected into the peritoneum of another have led to the development of *hepatolytic* serum; that is, serum which on injection into the body of an animal of the same species as that furnishing the liver cells induces noteworthy degenerative changes in the liver.

Thus, also, *nephrolytic*, *pancreolytic*, *thyreolytic*, *neurolytic*, and other analogous cytolytic substances have been developed.

So far as they have been studied, the nature of the active agents in these various cytolytic sera and their mode of action is analogous with those in hæmolytic sera. Here, as there, the action is due to two groups of substances: one, the "immune body," stable and increased by the adaptive process; the other, the alexin, occurring normally in the body, not increased in adaptation, and readily destroyed or rendered inactive by heat.

All of these last-mentioned forms of cytolytic sera require more extended study before far-reaching conclusions should be drawn from them. But it is now evident that the different functional types of cells in one animal are capable in the adaptation to the economy of another of inciting more or less definitely specific responses, as shown by the various types of cytolytic sera.

When one musters all the possible combinations

*It is necessary to reduce the temperature in this experiment, because at the ordinary temperature the integrity of the corpuscles would be destroyed through lysis.

in this form of adaptation and considers the probability that multiple immune bodies may develop in each instance, and that these furthermore may correspond to multiple alexins, the complexity of artificial cytolysis becomes sufficiently evident.

But now still another phase of this matter demands a word. These cytolytic or, as some prefer to call them, cytotoxic sera, when introduced into the living bodies of the species from which the cells inciting their formation are derived, act as toxins to which the organism responds, each after its kind, by the development of antitoxic substances. These are called *anticytolysins* or *anticytotoxins*.

Let me illustrate this interesting point. The blood serum of the normal guinea-pig has, as we have seen, no lytic action on the red blood cells of the rabbit, but after the adaptation of the guinea-pig to the blood of the rabbit by repeated intraperitoneal injections, the guinea-pig serum is strongly lytic for the rabbit corpuscles in test tubes outside the body. But this lytic serum is not less toxic when introduced into the body of the rabbit. Under these conditions the rabbit produces an antitoxin, an antihæmolytic substance which is in solution in his serum. If now a little of this antihæmolytic serum be mixed with some of the lytic serum from the adapted guinea-pig, it will be found, on the addition of rabbit corpuscles, that the lytic serum has lost its power, just as diphtheria toxin loses its harmful properties on mixture with diphtheria antitoxin.

Thus may be formed a great variety of specific "anti-bodies"—anticytolysins—from sera which are normally lytic or have become so through experimental adaptations.

In view of the remarkable results of the adaptation of the body to alien cells from different animal species which we have reviewed, it was natural to ask how an animal would respond to the introduction into the recesses of his body of cells—red blood-corpuscles, for example—from another individual of the same species. It was found, in fact, that under these circumstances lytic substances are sometimes, though not uniformly, developed. The possibility of the formation of *isolytic* substances was thus established.

But if this be possible, why may not *autolytic* substances be formed by the adaptation of an animal to his own cells experimentally displaced. Such substances have, however, not been found under the experimental conditions thus far observed.*

Still it is well known that cells and tissues worn out from use, or dead as the result of injury, inflammatory exudates, etc., are constantly removed from the living body by processes apparently analogous, if not identical with those which can be experimentally evoked. So that autolysis in some form seems to be an important factor in the maintenance of the integrity of the body. Just what the agencies are under which normal living tissues cells are protected from the action of autocytolytic substances is not yet clear. But the multiplicity of known "anti-bodies" justifies the conjecture that such substances—anticytolytic—may be constantly formed and act as safeguards to living and useful cells.

*Some observations are recorded in which, after profuse internal hemorrhage, hæmaturia has developed, indicating the possibility of autohæmolysis under special conditions.

If now we turn to the various hypotheses which have been advanced to account for the formation and action of these cytolytic substances, we find that an elaboration of Ehrlich's views as applied to antitoxin is here a source of great illumination. It is evident at once, however, that the matter is not as simple as in the case of antitoxin because we have here two substances at work, the immune body and the alexin. Neither the immune body nor the alexin alone can induce cytolysis. They must act together.

The phenomena are, in the main, accounted for if we assume that it is the alexin which when the necessary conditions are fulfilled exerts the destructive action upon the bacterial or animal cell. But the alexin cannot enter under ordinary conditions into direct chemical combination with the cell receptors. The union is effected only by the intervention of the substance which is increased in amount in the process of adaptation; namely, the immune body.

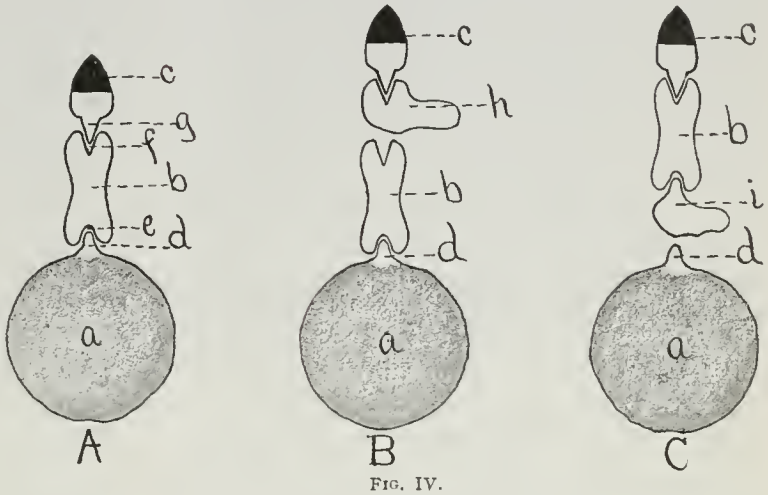

Fig. IV.

A long series of experiments has led to the belief that the immune body has two free atom complexes which enable it to form chemical unions. Through one of these atom complexes it unites with the cell to be destroyed; through the other it is joined to the alexin. Then and not until then is the alexin so linked to the cell that its toxic or destructive action upon the cell occurs.

This conception may be illustrated as in the case of antitoxin by crude figures.

Here it should be remembered we are illustrating not the production of the cytolytic substances, which we shall speak of later, but the action of them upon the cells to be destroyed.

Let *a*—Fig. IV.-A—be the cell which is to be destroyed with one of its receptors indicated at *d*. Let *b* represent the immune body with one atom complex *e* capable of uniting with the cell receptor *d*, and with another *f* capable of uniting with the alexin *c* through *g*. Now the alexin which appears to be the effective agent in the destruction, cannot unite directly with the cell receptor. When, however, it becomes linked to the cell by means of the immune body *b*, its destructive capacity can come into play.

In similar fashion one may indicate the action of anticytolytic substances which may be effective through union either with the alexin or with the immune body, as shown in Fig. IV, B and C. In B the "antibody" *h* prevents the linking of the alexin *c* to the immune body *b* by itself uniting with the former. It then acts as an antia'exin. In C the "antibody" *i* prevents the linking of the immune body *b* to the cell receptor *d*, and hence acts as an anti-immune body. We shall see in a

moment why at present the substance here spoken of as antialexin is usually called the anticomplement.

The experimental evidence that the anticytolytic substances may be thus due to the formation of adaptive substances of two classes, anti-immune substances and anticomplements, cannot be entered upon here.

In view of the rationale of cytolysis, as just set forth, we may consider the immune substance to be an intermediary between the alexin and the cell to be destroyed; or, on the other hand, we may consider the alexin as the complement to the immune substance, since only through their union is the toxic action possible.

In fact, following Ehrlich, one sometimes speaks of the immune body as the "*intermediary body*," or "*intermediary substance*," but since it is furnished with two combining affinities, it is now usually called the "*amboceptor*." Furthermore, since the experimental analysis of the lytic process by the new technique has shown that the germicidal and destructive action of blood serum, formerly supposed to be due to a single substance called alexin, is really due to the combined action of two substances, the use of the word alexin for one of them is misleading and has now been largely given up. The substance present in the serum of both normal and adapted animals through which lysis is effected when it is linked to the cell by the intermediary body is called the *complement*. Other names have been applied to these hypothetical complexes or substances which we need not now stop to consider.*

It was natural in the early studies on bacteriolysis which were incidental to researches on immunity, that the new substance which was found in the serum as the result of the immunizing process should be called the immune substance or immune body. It was natural also, although less appropriate, to apply the same term, immune substances, to the analogous substances which appeared in the serum as the result of the injection in the same fashion of cells and other materials which were not infectious, not disease producing, and against which, therefore, the body is not, in the old sense, immunized.

But these new uses of the word are, I think, unfortunate because the word immunity has come to have a special and useful significance in relation to infection, intoxication, and other conditions of natural or acquired tolerance to obviously and seriously harmful agents. The process in both instances is, indeed, one of adaptation, and the newly-acquired capacities of the serum are due to substances resulting from this adaptation. They arise from a functional modification of parts of the body, and hence may be appropriately called adaptive substances. It seems to the writer that it would be better to consider immunization as a special phase of adaptation, and so limit the application of the word that it shall still connote infection and intoxication in the traditional sense.

*These strange and multitudinous names are stumbling-blocks to those who have not followed step by step the development of these new lines of research. But most of them mark temporary phases in the development of the new conceptions and are no longer current. One should remember that immune bodies or immune substances, amboceptors, sensitizing substances (*substances sensibilisatrices*), or fixatives (*fixateurs*), and intermediary bodies or intermediary substances, all mean the same thing; and that alexin in its modern sense, *cystase*, addiment, and complement are synonymous; and, further, that for the expression of Ehrlich's views, the words *immune bodies* or *amboceptors* and *complements* suffice for practical purposes. (See Table showing synonyms, page 251.)

If we continue to speak of immunization to the countless possible adaptations of the body to such innocuous substances as milk, pepsin, white of egg, etc., we may be forced at last to regard intestinal digestion as immunization, and thus miss a distinction which is not without value in the expression of our conceptions of immunity to the infectious diseases.

This, then, is the rationale in accordance with Ehrlich's hypothesis of the action of these cytolytic or cytotoxic substances, either existing naturally, as they do in some animals, or being called forth in larger quantities in the process of adaptation to the cells which they destroy. This view has been most fully tested upon hæmolytic sera, since here the reaction is most easily studied. But so far as one can see it applies as well to the phenomena of bacteriolysis, whose direct study is much more difficult. It should, however, be borne in mind that the erythrocytes are very delicate and very peculiarly constituted cells, and it is possible that inferences drawn from hæmolysis are not applicable without qualification to other and less vulnerable cell types.

The origin of the amboceptors of these cytotoxic substances is accounted for in the same way as in the case of antitoxin. The cells or substances which are introduced into the animal, and to which it proceeds to adapt itself, lead, through union with such body cell receptors as may be fitted to them, to the overproduction of these special complex receptors. These are presently cast off as superfluous to the body cell producing them, and are then free as amboceptors in the body fluids.

As in the case of antitoxin formation, it is probable that the cell receptors which are thus increased are normally concerned in cell assimilation, and it is not unlikely that their complex character may have some relationship with the complexities of the great albuminous molecules, which must suffer initial changes before becoming fit for assimilation. At any rate this hypothesis assumes that in the process of adaptation either to toxic substances or to foreign cells or other albuminous material, the body develops no new capacities, but only an exaggeration of those already existing.

As to the exact source of the intermediary substances we cannot yet speak with certainty.

Phagocytosis.—It was inevitable that these remarkable studies on cytolytic sera should lead to considerable modification of the doctrine of phagocytosis; just as inevitable as that the recognition of the important offices of the cells in the formation of these lytic sera should lead to noteworthy concessions from the camps of the humoralists. I regret that the scope of this paper does not permit me adequately to review the later conceptions of Metschnikoff and his associates of the action of phagocytes in the adaptive processes by which immunity is secured.

Metschnikoff fully recognizes the importance of the adaptive substances, some of which may be largely increased in amount in the processes of immunization. More strenuously than other observers, however, he insists upon the phagocytic cells, especially the leucocytes, as the originators of the substances concerned in cytolysis, and holds that under ordinary conditions it is only within these cells that these substances are effective. In artificially immunized animals, however, the intermediary substances, it is conceded by Metschnikoff, may be set free from the cells which produce them and mingle with the body fluids. The complement, on the other hand, which he, in common with others of the French school, calls *cytase*, in recognition of its

ferment-like characters, Metschnikoff does not believe to be set free in the body fluids except through some damage to the leucocytes in which it is formed. Such a damage, for example, as befalls the leucocytes in the clotting of the blood: for in this process it is assumed that the setting free of the fibrin ferment involves the destruction—phagolysis—of the leucocytes.

The views advanced by Bordet and others of the French school regarding the union of the amboceptors with the cells to be destroyed are less precise than those of Ehrlich. Both, however, recognize the importance of an association of the amboceptor as a condition for the effective action of the complement (*cytase*). It is for this reason that the amboceptor is called by Bordet, Metschnikoff, and others the sensibilizing substance (*substance sensibilisatrice*) or the fixative (*fixateur*).

Finally, a long and ingenious series of experiments have led Metschnikoff and his associates to believe that there are two forms of *cytase*, one called *macrocytase*, formed by the macrocytes (large lymphocytes derived from the spleen, lymph-nodes and certain endothelial and connective tissue cells) and concerned in the destruction of animal cells, such as red blood cells, leucocytes, spermatozoa, various parenchyma cells, etc.; and *microcytase* derived from the microcytes (polymorphonuclear leucocytes), which is active in the destruction of bacteria.

The greatest diversity of view concerning the cytolytic process between Metschnikoff and his followers and the observers of the Ehrlich school relates to the question whether the complement (*cytase*) does or does not exist free in the blood plasma, for upon the answer to this question depends largely our belief as to the relative significance of intra- and extracellular cytolysis. This is one of the points concerning which more data is urgently needed. But even now the views of Metschnikoff are not inconsistent with the hypothesis of Ehrlich.

It is, in fact, most entertaining to observe the mutual felicitations of the exponents of the phagocytic and the humoral doctrines, each group being congratulated upon finding at last in the cherished fetich of the other the long sought clue to the solution of their common problem.

Agglutinative Substances.—But we have not finished with the tale of these curious adaptive resources of the living body when called upon to deal with foreign material of special character introduced in unusual ways into its recesses.

The phenomenon of agglutination has been known for several years, and especially widely known on account of its practical application in diagnosis. The general fact being that as an individual adapts himself—that is, becomes immunized, to a special bacterium or its toxic products, either in the course of an infectious disease or as the result of artificial processes, his serum, if placed under suitable conditions in contact with cultures of this special microorganism, may speedily immobilize the organism if it be motile, and whether motile or not, lead to its clumping into irregular masses.

This reaction has been used, as you well know, not only as a clinical test of special infections, but also as a means of differentiating species or varieties of bacteria. To most of us the term agglutination connotes Widal's test in typhoid fever. But recent studies have emphasized the fact that agglutination is a much more general phenomenon than has been commonly supposed, and is by no means limited to the sera of animals immunized against bacteria and bacterial products.

For example, in the adaptation of one animal to the red blood cells of another species, one finds that the serum of the adapted animal becomes not only lytic but agglutinative also for the corpuscles used for the injections. This is not only true in adaptation to red blood-corpuscles but to other cells as well. We have then to add agglutinative substances or agglutinins to our list of those which are developed in the body in this form of adaptation. (See Table, p. 251.) These also within the limits already set forth are specific.

Permit me to illustrate this point. I have in this first tube a little 0.85 per cent. salt solution, in which are a few beef-red blood cells. In the second tube is a little normal rabbit serum mixed with beef red cells. You see that the mixture in both tubes is homogeneous. There is no clumping. These two controls show that neither physiological salt solution nor normal rabbit serum are agglutinative for beef-red cells. In this third tube I have a 5-per-cent. suspension of beef corpuscles in salt solution. To this I add a few drops of the serum of a rabbit which has been adapted by successive intraperitoneal injections to beef blood cells. You observe the immediate clumping of the red cells, which float in visible masses as the tube is tilted to and fro. This serum then is agglutinative for alien blood cells. Finally, in this other tube is a suspension of the red blood cells of the dog. When I add to this some of the rabbit serum adapted to the corpuscles of the beef, no agglutination occurs, since the adaptation was to the cells of the beef and not of the dog. This test then illustrates the specificity of the agglutinating substances for erythrocytes.

Just as the specific red blood cells are capable of fixing the immune substance in lytic serum, so also the agglutinating substance may be fixed and removed from serum by placing in contact with the serum some of the corpuscles of the particular animal species under whose influence the agglutinative substances were formed.

While agglutinative substances are developed in the process of immunization, they are not , so far as we know, in any way protective. They seem to differ in many ways from lytic substances. Thus their activities are not suspended by a temperature of 56° C. They become inert, however, at about 70° C., and their agglutinating capacity is not restored by the addition of normal serum. It is inferred from this fact that the receptors concerned in agglutination are of simpler character than those through which lysis is secured.

The normal blood serum of some animals contains substances which are agglutinative for the red cells of other species. Thus normal beef serum is agglutinative for the corpuscles of the cat and rabbit. This capacity of the normal serum sometimes is, sometimes is not, associated with marked lytic capacity.

The mode of action of these so-called agglutinins is not yet very clearly understood, but a great many interesting facts have been developed in the studies on the general phenomena of agglutination which we cannot mention here.

Precipitating Substances.—There is still another way in which the body reveals adaptive alterations in the presence of foreign proteid substances. If a few cubic centimeters of the blood serum or exudate containing globulin from one animal be injected into the subcutaneous tissue or peritoneal cavity of another species, in repeated doses, it is found that, on adding a little of the blood serum of the adapted animal to a dilution of the fluid injected, a precipitate is formed. This reaction is also specific, save that in some instances body fluids from closely

related species, such as man and monkey, fowl and pigeon, sheep and goat, horse and ass, dog and fox, may both afford a precipitate. But this precipitate is invariably much more marked in the fluid used for adaptation than in the similar fluid from the related species.

This reaction is extremely delicate, it having been possible to recognize human blood in a dilution of 1-50,000.

By the use of this test, Nuttall, who has made very extensive observations, has been able to demonstrate in a most striking fashion phylogenetic relationships between animal species and groups of species, both warm- and cold-blooded, which have an important bearing upon classification.

The use of this precipitation test has been urged in forensic medicine to reinforce the present unsatisfactory methods of distinguishing between human and other blood. For if one have a rabbit or other animal artificially adapted to human blood from which fresh serum can be secured (even the dissolved dried serum will answer) he has only to dissolve in a little salt solution a suspected blood clot, and, mixing the two, observe the result. If under suitable conditions of dilution a considerable precipitate be formed, it is claimed that the suspected material could have been derived from no other animal than man. Since, however, it has been found that the blood not only of monkeys but of some other of the lower animals may give slight precipitates under these conditions, and since other human fluids containing albuminous substances, such as saliva, pus, inflammatory exudates, etc., may also give precipitates, it is evident that the result of this test should be interpreted with great caution.

The white of a hen's egg injected into the peritoneum of rabbits after a time gives rise to substances in the rabbits serum which induces a precipitate in fresh solutions of hens' egg albumen. No precipitate is produced by this serum in albumen solutions from the blood of the mammalia, and only a slight precipitate is formed in the egg albumen of related fowls, such as the duck, for example.

It has been shown that by the adaptation of the living animal to extracts of muscle tissue from another species, precipitating substances may be formed in the serum which are specific for the muscle used in the injection. Thus it is proposed to follow hard upon the trail of such malefactors as may turn horses into canned beef or dogs into sausages.

Milk of one animal thus introduced into the body of another gives rise to a substance in the adapted animal which causes a precipitate in the diluted milk used for injection, but not in the milk of another species, save sometimes in slight degree in milk from closely allied animals.

This reaction is also applicable to plant albumens. Thus, if an animal be adapted to a given species of bacteria, its blood serum on being added to the clear filtrate of the pure culture throws down a precipitate which is in some instances light, in others voluminous. This reaction is again specific, except within the group limits of related species. Thus, precipitating substances which are developed by the adaptation of the rabbit to the typhoid bacillus induce a slight precipitate in the culture filtrate of the colon bacillus, but not in the filtrate of B. *prodigiosus*, for example.

Numerous experiments have shown that other vegetable albumens call forth specific adaptive precipitins.

This precipitation-test is so delicate that it appears possible not only to distinguish the albumens from different animals and vegetable species, but to differentiate also some at least of the various albuminous substances in the individual.

The attempts which have been made to secure these adaptation products in the serum by the administration of special forms of albuminoids through the alimentary tract have been, for the most part, unsuccessful.

Finally, it is worthy of note that it has been possible by the adaptation of a fresh animal of the appropriate species to these precipitating sera to obtain "antibodies"; in the case of milk adaptation, for example, by the use of the so-called lacto-serum, to secure an antilacto-serum capable when added to the test fluids of preventing the formation of the specific precipitate.

A great deal of most careful research has been devoted to the nature of the precipitating substances which the scope of this paper does not permit us to touch upon. But it should be said that in their resistance to heat and in other ways the precipitating substances appear to be more closely related to agglutinating than to lytic substances.

The sera of cold-blooded animals, like those of the warm-blooded, contain, under normal conditions, hæmolytic and agglutinating substances, as shown by the recent studies of Noguchi. Furthermore, the experiments of v. Dungern show that in the cold-blooded animals also the precipitating substances may be increased by the injection of alien blood plasma.

Although we have considered separately the development in the body of cytolytic, agglutinating, and precipitating substances, it should be remembered that these may be formed together in the same animal.

The effects of foreign cells and their derivatives upon whatever body cells produce the lytic, agglutinating, and precipitating substances is apparently not lasting, since if the injections be suspended they gradually disappear from the serum. The time of their disappearance, however, like that of appearance, is not regularly the same, even in the same animal.

If now we draw together these devious lines of research which I have so hurriedly and so superficially traced, we find that the living body is capable of adapting itself to certain foreign materials introduced into its recesses, by the formation of various substances, for the most part specific in their relationship to the materials which called them forth. These substances may be tabulated, following the plan of Aschoff, as on page 251.

Welch's Hypothesis.—Among the new researches relating to immunity none have been more interesting and suggestive than those which deal with the toxins and their baleful effects in the living body. With the new technique and the delicate tests which are now at command, applicable without as well as within the body, we may confidently expect new light upon some of the most obscure problems of infection and intoxication.

In view of the recent valuable summary of Welch in the Huxley Lecture for 1902, which treats with especial fulness this subject of bacterial and other toxins and their relationship to various pathological processes, I need not dwell upon the subject here. But I would not fail to call your attention to the hypothesis advanced by Welch in this lecture to account for the very significant fact that the toxins developed by many species of bacteria when within the living body seem to be far more potent than those which it has been possible to secure from the same sources in artificial cultures outside of the body.

TABLE SHOWING VARIOUS FORMS OF ADAPTATION PRODUCTS, WITH THEIR RELATIONSHIPS AND SYNONYMS.

A

The body-cells in adaptation to alien substances of protoplasmic origin may elaborate—	Antitoxins, Antiferments,		Formed of two substances.	**Complement:** Alexin, Addiment, Cytase. **Amboceptor:** Immune body, Intermediary body, *Substance Sensibilisatrice*, *Fixateur*, *Präperateur*, Copula, Desmon.
	Cytolysins, (Cytotoxins),	Hæmolysins, Bacteriolysins-bacteriocidal substances. Special Cytotoxins: Spermatoxin, Nephrotoxin, Hepatotoxin, etc.		
	Agglutinins, Precipitins.			

B

The "antibodies"	Cytotoxins, Agglutinins, Precipitins,	may lead to the formation of "anti-antibodies."	Anticytoxins	Anticomplements. Antiamboceptors (anti-immune bodies).
			Antiagglutinins. Antiprecipitins.	

Welch's hypothesis may be outlined as follows: If it be true, as the view of Ehrlich assumes, that the living body cells when brought into intimate relationship with microorganisms or their toxic products in infection or immunization are capable of adapting themselves to the new conditions by the elaboration of protective substances—bacteriotoxins—especially potent to harm the invading organisms, may it not also be true that these invading organisms in their turn—being even as the body cells are, living structures capable of adaptation to a harmful environment—have the power of self-protection through the development of substances—cytotoxins—of exalted potency: substances which are protective to the microorganisms through the damage which they inflict upon the living body cells? Such substances, finding in the body their necessary complements, may not only neutralize and render futile the protective substances which the body cells elaborate by direct union with them, but may also induce toxic effects of the severity of which our studies on the toxins of artificial cultures give us no adequate conception. This ingenious hypothesis opens a new field for research which may hold the key to many subtle and obscure problems of infection.

If I have succeeded in this hurried survey of these newly opened fields of research, it is clear that we are face to face with problems of the highest theoretical interest and importance, and that in the achievements of the last decade lies abundant inspiration for the immediate future. But I fancy that I shall not have fully absolved myself from the exigencies of the practitioner's outlook unless I shall point to some of the directions in which this new lore may become available in the ministrations of the physician. In this I must perforce be brief, for in truth the outlook is chiefly one of promise, and much patient research will be required before the bearings and relationships of these new conceptions shall have been co-ordinated and rendered available in either the prevention or the treatment of disease. But two or three points I shall venture to touch upon.

We are first led back to the great group of infectious diseases in which, as it now appears, the protective agencies in both natural and artificial immunity are not chiefly antitoxic but bacteriolytic.

In the light of the new knowledge of cytolytic sera, and the conditions under which these may be effective, the promise of serum therapy, so long limited to antitoxic immunity, seems now to be definite and encouraging. Let me develop one of the new possibilities.

We have seen in our review of hæmolysis that hæmolytic serum heated to 56° C. loses its lytic power owing to the destruction of the very labile complements. We have seen further that this power is restored by the addition of a little fresh serum from a normal animal; that is, a serum-containing complement. Now it has been found that this "reactivation" of the serum, as it is called, can often be brought about by the sera of various animals. Thus, for example, the serum of the guinea-pig adapted to the erythrocytes of the rabbit is lytic for these cells of the rabbit. If such sera be heated to 56°C. it is no longer lytic, the activities of the complement are destroyed; but the serum can be reactivated by a little fresh serum not only from a normal rabbit, but from the goat and the rat. The serum of many other animals, however, is ineffective under these conditions. The reason for this, of course, in accordance with Ehrlich's hypothesis, is that the complements of the reactivating sera have combining capacity with the special amboceptors, and so can become effective, while in other sera, the linking of the complement to the red cells through the amboceptors being impossible, there can be no restoration of the lytic action.

It is not difficult to secure immune substances (amboceptors) by the adaptation of animals to various kinds of pathogenic bacteria. These may be formed in such abundance as to be out of proportion to the complements. But unless these immune substances when injected into the body for protective purposes either carry with them or find in the new environment an abundance and appropriate forms of complements, they are not wholly available in destroying bacteria. One of the great problems of the immediate future, then, so far as serum therapy is concerned, seems to be to secure suitable complements to act with immune substances if the former do not exist in the human fluids, or to reinforce these substances from the sera of suitable animals if the human stock be scanty.

The search then for bacteriolytic sera takes on a wider range, and it is not unlikely, in the opinion of Ehrlich, that the nice adjustment of immune substances and complements which must characterize

the most effective bacteriolytic sera will be secured rather by a combination of sera from various animals than from a single animal.

There is, however, much ground for believing that in order to be most effective the complements with which we may seek to reinforce the potency of bacteriolytic sera should come from species closely allied to our own.

It is possible, therefore, that our blood relation, the monkey, may win at last, through his contributions to the pharmacopœia, some measure of esteem which, by reason of the scruples of the church and his objectionable personality, has been so long and so unjustly withheld.

If the securing of an appropriate complement is thus of such importance in the attempt to prepare bacteriolytic sera for therapeutic purposes, the maintenance of sufficient complements in the human body must be of the utmost significance in its intrinsic protective mechanism against infection. That this consideration is not without support in fact is shown by the studies of Abbott, Longcope, and others, who have found that after the continuous administration of alcohol and in various chronic as well as acute diseases, the amount of complement in the blood may be notably reduced. We have thus a distinct and definite contribution to our knowledge of one of those factors in predisposition to infection which, in a general way, are so fully recognized, but which are, for the most part, but ill-defined and little understood.

One other point deserves brief mention here. If it be possible so to adapt an animal to a particular form of cells that its serum shall become specifically lytic for these cells, may we not have here a possible outlook for the preparation of sera which will be effective in limiting the growth if not of locally destroying malignant or other tumors? But few experiments have been done with this end in view, and these appear to afford little encouragement. It is possible that with a fuller knowledge of cytolysis the outlook will be more promising. But a great amount of preliminary research must be carried out before the problem can be confidently approached.

The hypothesis of Ehrlich, which so closely correlates the action of toxins with the assimilation of nutrient stuff, has led to new conceptions of the details of the relationship of foods transformed by the preliminary digestive process to the material which is finally placed at the disposal of the cells. It seems not unlikely that through the action of the cell receptors the food material which arrives in the body fluids may not only be adapted to the specific uses of the cells, but that by the formation of countless varieties of substances analogous to the so-called "antibodies" of immunization, the cells are protected against equally various toxic substances. If this be true, the hope seems justified that following the lines of research suggested by this new technique we may be able ultimately to understand more clearly the details of the so-called internal secretion and those disturbances of chemical adjustment which give rise to many important phases of autointoxication.

To sum up the whole matter, then, we have reason to believe from our present knowledge that immunity is either antitoxic or bacteriolytic, and that the two protective processes may often act together.

It appears probable that bacteriolytic immunity is dependent upon the mutual action of two groups of substances, one amboceptors or immune substances which may be specifically increased by artificial adaptation; the other—complements—existing already formed in the normal animal, either free or within certain types of cells.

There seems to be abundant ground for the belief that the protective agencies which are evoked in both natural and artificial immunization are simply those which the body makes use of in its normal metabolism, exaggerated and diverted to different ends, it is true, in the face of emergencies, but giving evidence of the birth of no new physiological capacities.

The new methods of research and the far-reaching conceptions which they have stimulated and fostered seem likely to mark a new era in physiological chemistry, and to link more closely than any other extension of knowledge in our time some of the most subtle and urgent problems of medicine to the wider outlooks of general biology.*

*BIBLIOGRAPHY.

The records of these recent researches are widely scattered through the German, French, and English technical periodicals.

The summary of Aschoff (Ehrlich's Seitenkettentheorie und ihre Anwendung auf die künstliche Immunizierungsprozesse. *Zeitschrift für Allgemeine Physiologie.* Bd. I. Heft 3; 1902) is most complete and contains a full bibliography. The monograph of v. Dungern (Die Antikörper, 1903) contains much valuable material.

In English, the recent Huxley Lecture by Welch (Recent Studies of Immunity. Reprinted in the *Medical News*, October 18, 1902; and in *Science*, November 21 and 28, 1902) is admirable, and deals with especial fulness with toxins and their relationship to various important pathological processes.

Ritchie's discussion of the subject (*The Journal of Hygiene.* Vol. II, Nos. 2, 3, and 4, 1902) treats in a clear and philosophical fashion the facts and hypotheses involved, and contains many valuable suggestions for further research.

THE PROBLEM OF EPILEPSY: SOME SUGGESTIONS FOR ITS SOLUTION.*

By L. PIERCE CLARK, M.D.,
NEW YORK.

CLINICAL ASSISTANT AT THE VANDERBILT CLINIC (COLUMBIA UNIVERSITY), NEW YORK; FORMERLY FIRST ASSISTANT PHYSICIAN AT THE CRAIG COLONY FOR EPILEPTICS, SONYEA, NEW YORK.

AND

THOMAS P. PROUT, M.D.,
NEW YORK.

CLINICAL ASSISTANT IN THE NEUROLOGICAL DEPARTMENT AT THE NEW YORK HOSPITAL DISPENSARY; FORMERLY SECOND ASSISTANT PHYSICIAN AND PATHOLOGIST AT THE NEW JERSEY HOSPITAL FOR THE INSANE, MORRIS PLAINS, NEW JERSEY.

THERE is now some sort of special provision established for the epileptic class in nineteen States. In each of these institutions adequate systems of segregation, occupation, and education of the patients are in course of more or less complete installation. With the accomplishment of these primary and important tasks, attention must be directed toward solving the problem of the real nature and treatment of the disease. As the application of a rational therapy awaits the discovery of the lesion and its method of production, the importance of the work is obvious.

In relation to their order of occurrence, we will briefly consider the questions involved in this problem: (1) What is the nature of the organic anomaly, the material basis of the predisposition? (2) What is the immediate excitant operating upon the predisposition? (3) What is the seat and the nature of the lesion?

Some of the gross organic anomalies lie in the existence of rickets, cerebral palsy, various forms of injury, hemorrhage, embolism, alcohol, syphilis, both inherited and acquired, and the vague but none the less important hereditary instability of the cerebral cortex. Again the various deformities

*Read at the annual meeting of the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics, New York, November 5, 1902.

and abnormalities of development of the organism shown in the persistent thymus, stigmata of degeneration, and an inadequate vascular system are but evidences of the maldevelopment of the individual as a biologic unit, in which imperfection the nervous system surely participates. The particular character of the cortical cellular anomaly is not known. We suggest, however, that animal experimentation be one of the means used for clearing this point, especially to determine the nature of the morbid cell anatomy, chemistry, and physiology. The work should be done in part at least upon hereditary and induced epilepsies in animals; 50 to 80 per cent. of the progeny of such animals ultimately become epileptic, as proven by Obersteiner and Sommers. Normal control studies should also accompany the work. By examining a part of the progeny before and after the epilepsy developed, light would be thrown upon the state of the cortex before and after the disease in a progeny known definitely to be predisposed. The nature of the excitant and counteracting principles of treatment would also be suggested coincidently.

In considering the development of the disease, we believe the excitant is a toxic or autotoxic agent for the following reasons: First, the lesion is a general one affecting the entire cortex; second, it involves most extensively the cells of the second or so-called pyramidal layer type, the cells which present a relatively larger surface exposure to the circulating poison in proportion to their volume than the large pyramids; third, the presence of a marked neurogliar proliferation; fourth, the changes in the cell are quite analogous to those definitely known to be caused by toxic agents, as furfurol, alcohol, and the tetanus bacillus and its toxins.

Further study in physiological chemistry, experimental pathology, and allied studies must be undertaken to isolate the exact toxic agents, care always being exercised in maintaining normal controls and excluding the *products* of the disease from those *causing* it.

Researches should also be undertaken not only upon faulty gastrointestinal changes in the foods, but upon the liver and its secretions and the blood-modifying organs.

That the seat of the lesion is in the cerebral cortex we believe all are agreed, therefore its evolutional history, ascending through its past cycles of being considered successively as a muscular peripheral nerve, cord, medullary, basal ganglia cerebellar, and, finally, cerebral affection, however interesting, will not be touched upon here.

As to the nature of the lesion: We have during the last six years examined the cortex histopathologically in twenty-one cases from the Craig Colony, under what are considered at present ideal conditions and methods; nine cases were of status epilepticus, occurring in organic and idiopathic epilepsies; these were of serial epilepsy—three died during single seizures, and six died of coincident affections independent of their disease. The same lesions were uniformly found present in all. The lesions differed only in degree, not in character. The changes were most marked in the status, as it is the maximum intensity of the disease, the true climax of epilepsy. The evidences of cortical degeneration were general. The expression of acute and chronic exhaustion were shown in a diffuse chromatolysis and other characteristic protoplasmic changes.

The manifestation of a vital intoxication of the cell was presented in a swollen nucleus, a destruction of the nuclear membrane and intranuclear network, and, finally, an abstraction of the nucleolus was rendered easily possible by the knife, it behaving as a loose body in the nucleus.

Contributory evidence of the ultimate disappearance of the cell from the cortex was manifest in an infiltration of the cortex with leucocytes and a progressive gliosis. Controls in the normal human and animal brain were employed throughout the study. The recent or primary lesion of epilepsy is a cell destruction, while the remote or secondary one is of a gliosis, a sclerosis more or less diffuse of various cortical areas. From the nature of the lesion we infer that epilepsy is a highly sensory motor reflex phenomenon. It is primarily sensory with a motor expression. The nervous discharges are not only transmitted over the motor tracts, but also over others for motor reflex impulses, as demonstrated by Starlinger, Bischoff, Prus, Hering, Redlich, and Rothman. These tracts, from a functional point of view, have been called by Prus extrapyramidal tracts.

The interpretations of these findings, pathologically and clinically, is interesting in the extreme. It is a well-known biologic fact that the nucleus presides over vital processes of the cell. Its destruction ultimately causes the disappearance of the cell as a functionating body from the cortex. Commensurate with its destruction, dementia and paralysis in effect result. The lesion is not confined to epilepsy alone; indeed, quite similar changes are found in myoclonus, general paresis, chorea, and the like degenerative cortical disorders. The data, however, are of sufficient proof that the lesion of epilepsy is a diffuse and profound cortical degeneration, and we believe every well-marked case of epilepsy will show these lesions in some degree, depending upon the varying factors of preparedness of soil and the severity and persistence of the excitant.

In order that these and similar problems as to the nature and pathology of epilepsy shall be investigated, it is necessary that workers in the special institutions for epilepsy be enlisted. It is essential that proper places for such workers be established. There should be built in every colony and hospital for epileptics a special building for the reception, observation and study of all newly admitted cases, a clinico-pathological hospital, fashioned much on the admirable plan of the psychopathic hospitals abroad for the study of the acute insane. Naturally, rational therapeutics, principles in dietetics, massage, and hydropathy, would find their proper place here also. After due and exhaustive study of each case, the patients may pass from the observation ward and laboratory to the less restricted confines of the colony proper for continued application of treatment in its broadest sense. We would then have a reception hospital for all acute cases and the colony proper for the continued observation and treatment.

The field of research is too vast; the problem too intricate for any one set of workers to cover the ground. We would, therefore, suggest that all investigations in the several institutions for epileptics should be arranged on a definite scientific plan, so that a correlation of the results may be made from time to time. Such a co-operative scheme could be best put into effect by the establishment of a central scientific advisory committee.

We venture to prophesy that there is no one disease whose careful study in the near future will contribute more to the elucidation of the obscure points all over the broad field of neurology and psychiatry as that of epilepsy. Indeed, Hughlings-Jackson has made the greater part of his marvelous discoveries of the laws underlying the structure and function of the nervous system during the past

thirty years almost solely through the study of epileptic seizures.

To summarize in conclusion: We submit that epilepsy is a disease resulting in diffuse and profound cortical degeneration; a highly complex sensory motor phenomenon, primarily sensory with a motor expression. The lesions attending its course are shown in the following: Swollen nucleus, destruction of the nuclear membrane and intranuclear network; easy abstraction of the nucleolus by the knife, as it becomes a loose body in the nucleus; diffuse chromotolosis, and other protoplasmic changes. All these lesions result in the ultimate disappearance of the cell as a biologic unit and its replacement by a gliosis. The lesions are induced by a toxic or autotoxic agent operating upon an organic anomaly of the cerebral cortex which forms the predisposition.

We urge, therefore, the construction of special accommodations for the reception and study of each newly admitted case of epilepsy in the colonies, and hospitals which shall be arranged on similar lines to the psychopathic hospitals abroad, and we finally suggest that some central scientific advisory committee be appointed to formulate a correlated plan for future study and research.*

*At the completion of the paper microscopical slides and camera lucida drawings were shown in demonstration of the lesion of epilepsy as detailed in the article. Reproduction of the same here was impossible, as they form a part of the authors' monographic research study now in press.

THE RADICAL CURE OF INGUINAL HERNIA WITH LOCAL ANÆSTHESIA.*

By J. A. BODINE, M.D.,
NEW YORK.

ADJUNCT PROFESSOR OF SURGERY, NEW YORK POLYCLINIC; ATTENDING SURGEON, ST. JOHN'S HOSPITAL, LONG ISLAND CITY.

It is estimated and accepted that 5 per cent. of our male population is ruptured. It would be of equal interest to know what percentage of these seek aid from sources other than the surgical profession. Certain it is, a flourishing army of truss-adjusters attest the fact that we have not offered a method of cure entirely satisfactory to the public. From the surgeon's standpoint, few operations are so satisfactory as the radical cure of an average-sized inguinal hernia. From the view-point of the patient, it evidently appears less attractive—and he prefers, rather than submit to operation, to carry with him an actual disability and a potential death.

The reasonable certainty of cure and short detention from business which we offer must be encouraging to a patient, and no doubt the majority would be operated on if a danger to life (which though small) were not in conscience to be added to our proposition. This danger in herniotomy is represented alone by the danger of general narcosis, hence it is the anæsthesia that becomes the deterrent factor to the patient. With this premise, I feel assured of your interest in the recital of forty-eight cases of radical operation for inguinal hernia without general anæsthesia.

In all the cases, muriate cocaine was used as a local anæsthetic, and in no instance was one-half of one grain of the drug exceeded; consequently danger to life was eliminated.

A moment's thought of the anatomy involved will convince one that herniotomy is peculiarly well adapted to local anæsthesia. The operative area lies superficial. Scarcely ever is ligation of a bleeding point demanded. Intraperitoneal or visceral work, if needed, is of short duration, and usually simple in character, and, lastly, and of greatest importance, the sensation of the entire field of work is presided over by three trunk nerves. These are superficially placed and easily found.

The problem, then, is to find these nerve trunks, and with a few drops of cocaine solution injected within the nerve-sheath abolish pain sensation within the entire field of work.

The hypogastric branch of iliohypogastric, inguinal branch of ilioinguinal and genital branch of genito-crural are the three nerve trunks in question. They have been named in the order of their pain-bearing importance, also in the order of their constancy of anatomical position.

All three nerves are derived from the first and second lumbar, and participate slightly in forming the lumbar plexus. They possess intercommunicating branches, which explains why the operation may be completed with comparatively little pain, after cocainization of the iliohypogastric, though the other two are not identified. The anatomy of these nerves prior to their entrance upon the inguinal region does not interest us. The largest, most constant, and easiest found is the iliohypogastric. It runs from the iliac crest inward, just beneath the apponeurosis of the external oblique muscle. It may lie on the internal oblique, just above the arching fibers of the internal ring, or across the front of the hernial coverings as low as the external ring. If it is large, one or both of the other two nerves may be absent, and little time should be spent in their search. The ilioinguinal, as stated, is absent in a certain proportion of cases. In situation it is less constant, and, in fact, occupies many different positions. Generally it lies at a lower level than the iliohypogastric, and parallel to it in direction. Again it frequently runs to the outer side and parallel to the long axis of the hernial protrusion. The genito-crural is also unfaithful in position, and often not identified during the operation. It most frequently emerges from the internal ring with the hernial protrusion, lying between the cord and hernial sac. An apology is due you for this imperfect and unsatisfactory anatomy. Yet you will obtain even less information by consulting textbooks on the subject. A special study of the location and direction of these nerves is here promised in a future communication.

The uncertainty in situation of the last two nerves would be discouraging if their identification were essential to the success of the operation, but if the iliohypogastric is found and cocainized, the pain can be almost entirely controlled by occasional infiltration into areas known to be sensitive. Frequently a white, fibrous cord, the remnant of fetal peritoneum is found running along the front of the hernial coverings and looks not unlike a nerve. It should not be mistaken for the ilioinguinal.

In forty-eight cases all three nerves were identified seventeen times—the iliohypogastric and ilioinguinal twenty times—the iliohypogastric alone forty-eight times.

Technique of Operation.—In the effort to avoid bleeding points, wide dissection, and to secure precision, the textual description, of the operation has been modified in certain steps. Of very greatest importance is the length to which the lower end of the skin incision is extended. While it may be started as high as desired, it should stop at the lateral end of the suprapubic skin-fold. This incision we may deepen to our operative field without encountering a vessel sufficiently large to demand a ligature, while if the incision be extended an inch lower from six to thirteen catgut ligatures will be required to tie the bleeding points. Not only is this catgut, when

*Read at a meeting of the New York State Medical Association, October 23, 1902.

softened by the tissues into gelatin, an invitation to sepsis, but in cocaine work it means six to thirteen acute twinges of pain in the *beginning* of the operation. There is a fatal difference between pain at the outset and equal pain near the end of the operation. The one destroys the confidence of the patient in our assurance of immunity to pain and may utterly demoralize him, while the other is borne with equanimity because the termination is at hand. Whenever a blood vessel is cut or tied in cocaine work it produces acute pain.

The incision so placed gives ample room by downward traction of the mobile skin, and nearly always permits completion of the operation without the use of a ligature. This is repeated, for emphasis, on account of its importance. The line of incision in the skin is cocainized by introducing the needle just under the scarf epithelium. It is in this plane of the skin that the highly differentiated end-organs of the sensory nerves lie. When the needle point lies true it can be seen from the surface.

This anæsthesia will permit the incision to be painlessly deepened to the apponeurosis of the external oblique. This structure is infiltrated with a much weaker solution, especially into the arciform fibers around the external ring, where lie the terminal ends of the ilioinguinal nerve. Upon splitting and reflecting the external oblique, the iliohypogastric nerve is seen in the situation stated, and cocainized as described. The ilioinguinal is also sought, but if not found, infiltrate the hernial coverings in a straight line over neck of sac and deepen incision until this structure is reached. The neck of sac, also margins of internal ring, should now be infiltrated and the sac incised. The visceral contents are returned to abdominal cavity by Trendelenburg posture.

If omentum is to be excised, it is gently withdrawn, ligated, and amputated without additional cocainization, and, in my experience, without pain. Forcible traction on the omentum produces pain, referred to the stomach, and may even induce nausea. Specific instances of visceral handling will be detailed later. A *dry* pad, if large, inserted through the peritoneal opening, produces pain from friction against the parietal peritoneal reflection. The hernial contents having been treated, the neck of the sac is gently separated from the cord (a look-out being kept for the genito-crural nerve) and amputated; leaving the sac-fundus lying in its bed. After transfixion and ligation of neck, the fundus is caught, on its cut edge, by two or more equi-distant artery clamps, and wig-wagged from its bed. Even old, thick sacs may thus be liberated with an occasional snip with scissors. If the three nerves have been cocainized, the remainder of the operation is entirely without pain, but if only the iliohypogastric has been found, some infiltration will be needed into the conjoined tendon. The cord is lifted from its position and the operation concluded according to Bassini.

Two suggestions of proven worth are offered: (1) If a strip of dry gauze is used to hold up the cord it may, during the necessary manipulations, roll the cord on its long axis, and exposure to air causes agglutination in this position of torsion. A wetted strand of catgut as a retractor will obviate this danger. (2) The deep sutures should include in the bite only one-half the thickness of the conjoined tendon. This gives perfect apposition to Poupart's ligament, and does not induce pressure necrosis with cutting out of stitch, because blood supply is not endangered.

The Cocaine Solution.—One-fourth of one per cent. solution is used for the skin and nerve trunks while for all sub-dermic infiltrations one-tenth of one per cent. is sufficiently strong. When intra-neural anæsthesia cannot be obtained infiltration must be used. This holds good in all cocaine surgery. It is essential to use a weak solution, as we cannot infiltrate with a two-per-cent. or a four-per-cent. solution for fear of cocaine poisoning. A one-fourth of one per cent. solution, when properly infiltrated, will completely anæsthetize the skin for one hour and a half. When a two-per-cent. solution of cocaine is used, one-fourth per cent. anæsthetizes sensation, while the remaining one and three-fourth per cent. goes to intoxicate the patient.

It is confusing at times to use solutions computed by per cent. A better way is to dissolve a one-grain tablet in two drachms of boiled water, which approximates one per cent. in strength, and then dilute this as needed, in the syringe, with sterile, warm water. The amount of cocaine that has been used can be told at any stage of the operation by what remains of the original two drachms. This saves troublesome mathematics. Cocaine solutions should always be freshly made at time of operation and used warm. In six hours a fungus begins to form, and the solution is potentially septic; in twenty-four hours it is distinctly septic and will produce suppuration. A sterile solution of cocaine does not interfere with wound healing any more than does salt solution. Again, a solution tends to become acid and loses in anæsthetic value. We have never used morphine prior to operating or in the cocaine solution as does Schleich. It is reserved to relieve pain after operation.

A descriptive recital, in detail, of the cases would be monotonous and unprofitable. All were inguinal hernias, in patients ranging in age from sixteen to seventy-six years. Five were strangulated, and these were slightly more painful than the non-strangulated. I believe this greatly due to vitiated morale of patients. In one of these cases fully sixteen or eighteen inches of intestine were withdrawn and freely handled—pain not complained of—while in another of this group considerable complaint was made against the application of hot cloths to the intestine.

Of the forty-three non-strangulated cases six had thick, adherent sacs, requiring scissors and gauze rubbing to separate the cord. In five cases the omentum was ligated and excised. In one case the amputated omentum weighed sixteen ounces, and was ligated in sixteen sections. There was absolutely no pain in this manipulation. The appendix was adherent to the sac in one case, and was painlessly amputated—stump inverted and sutured—without additional cocainization. Three cases were of the congenital type. In one case, with thin muscularis, Bloodgood's transference from rectus was easily accomplished. The remainder were simple cases, without complications.

In eighteen cases there was entire absence of pain; in twenty-eight the pain may be characterized as moderate, and in two it was acute when ligating the neck of the sac. In three cases of double hernia, which are classed above as *moderate* in pain, the second side was done with local anæsthesia at the patients' request.

Dr. Morris of Pontiac, Mich., had a small nasal spur removed under cocaine two days before his herniotomy. He declares the pain was infinitely greater in the nasal operation. Three other physicians express the pain as less trying than the nausea after ether.

In conclusion, we are nearly convinced that the usual textual advice of using cocaine when ether is contraindicated should be reversed.

128 East Thirty-fourth Street.

Albuminous Expectoration Following Thoracentesis, with Report of a Case.—Herbert W. Allen describes this case. The patient was a man twenty-five years old, admitted to the hospital with pleural effusion. He was tapped three times. Toward the close of the last operation the patient complained of shortness of breath and of a smothering sensation. After about half an hour there began a series of severe paroxysms of coughing, each being followed by profuse expectoration of serous, frothy sputum. The paroxysms followed each other at very short intervals, and the patient complained much of dyspnœa. The symptoms gradually subsided after lasting about an hour, but the patient expectorated for two or three hours longer. The total amount of expectoration was not accurately measured but approximated one liter. It was very frothy, of a pale green color, translucent, and on standing deposited a muddy sediment. Treated with nitric acid it gave an abundant precipitate of albumin. Examined microscopically it contained large numbers of bacteria, many flat epithelial cells, a few red blood-corpuscles, and some polynuclear leucocytes. A differential count of the leucocytes in the effusion showed: polymorphonuclear leucocytes, 1.7 per cent.; large mononuclear leucocytes, 1.9 per cent.; small mononuclear leucocytes, 96.4 per cent. No tubercle bacilli could be found in a centrifugalized specimen. The subsequent history was satisfactory, and there was no reaccumulation. Four main theories have been advanced to explain the phenomenon of albuminous expectoration: (1) Perforation of the lung by the trocar. (2) Spontaneous perforation of the lung. (3) Reabsorption of the fluid remaining after thoracentesis. (4) Acute œdema of the lung. The last theory is the one accepted to-day by most observers. The exact mechanism by which the lung œdema is produced must still be left an unsettled question.—*Bulletin of the Johns Hopkins Hospital.*

The Prevention of Pneumonia.—In an address on Pneumonia, recently delivered before the Michigan State Board of Health, Dr. Reynolds, Health Commissioner of Chicago, formulated the following rules looking to the reduction of the mortality from this disease: (1) It is well known that pneumonia is a highly contagious disease, the cause of which is a microorganism in the sputa of those suffering from the malady, and that it is contracted by inhaling this germ. Therefore, the same care should be taken to collect and destroy the sputa that is taken in pulmonary tuberculosis, or in diphtheria or influenza. (2) During the illness the greatest pains should be taken to prevent soiling bed-clothing, carpets, or furniture with the sputa, and after the illness the patient's room should be thoroughly cleansed and ventilated. (3) The fact that the disease is most prevalent in the winter season, when people are most crowded together and live much of the time in badly-ventilated apartments, makes obvious the necessity of thorough ventilation of houses, offices, factories, theatres, churches, passenger cars, and other public places, in order that the air which must be breathed may be kept clean and free from infectious matter. (4) Laymen should be taught not to be afraid of a patient who has pneumonia, influenza, or tuberculosis, but to be afraid of lack of cleanliness about him during his illness, of failure to enforce prophylactic measures and of close, badly-ventilated apartments during the season when these diseases most prevail. (5) Since pneumonia is most fatal at the extremes of life—the young and the aged—special care should be taken to guard children and old persons against exposure to the infection of those already suffering with the disease and against cold, privation, and exposure to the weather, which are potent, predisposing causes.

Surgical Features of Typhoid Fever.—Thomas McCrae and James F. Mitchell summarize their two years' experience in typhoid fever: (1) Two hundred and seventy-five cases have been treated. (2) Of these a certain number had unimportant complications, as boils or abscesses, the cultures from which, in every instance, yielded pyogenic cocci. (3) Periostitis and perichondritis have been seen occasionally, always subsiding without surgical interference. (4) Glandular affections, especially mastitis, occurred, but were not serious. (5) Abscess of the liver occurred once with recovery, the cultures being practically negative. (6) There have been symptoms of cholecystitis in five cases, of which three subsided without operation; one was operated upon and recovered; while in one the gall-bladder ruptured and general peritonitis, resulting in death, followed. (7) Appendicitis was suspected on admission in three cases and developed once during the course of typhoid fever. (8) Perforation of the intestine occurred eight times. Of these, seven were operated upon with two recoveries, a third dying of toxæmia after a week. All of these seven were recognized within nine hours, except two in which hemorrhage from the bowel accompanied the perforation. In one case operation was not advised because the patient was evidently in extremis. (9) Exploratory laparotomy was done in two cases in which no perforation was found. In one the symptoms proved to be due to intestinal hemorrhage; in the other to a low grade of peritonitis. The first died; the second recovered. (10) Eleven cases with suspicious abdominal symptoms were not operated upon. Of these, two died and the autopsies showed no perforation. The remaining nine recovered.—*The Johns Hopkins Hospital Reports.*

Diet in Rheumatism.—G. O. Jarvis thus sums up the result of his researches: Allow a liberal meat diet, cooked by being either broiled or roasted, and served rare, because well-cooked meats are not easily attacked by the digestive juices. They should not be boiled until all the salines have been dissolved out of them. Eat carbohydrates in moderation, cooked so as to preserve the salts (that is to say, by frying in an excess of boiling oil), and selected so as to avoid those likely to undergo pathologic fermentation in the digestive tube. Fats in rather small amounts. Water should be drunk plentifully, and it should be especially directed that some water be taken between meals. Alcoholic drinks, tea, and coffee are to be used in great moderation, say one cup of tea or coffee daily, and alcoholic drinks not at all, or, if prohibition be impracticable, according to the individual temperament, and bearing in mind that malt liquors are generally worse than wines or diluted liquors. Results in lithemics treated upon this basis have been good, and of forty-five cases of trigeminal neuralgia not one has been lost sight of until cured. These cases are mentioned because it seems to the author that nearly all cases of facial neuralgia have a rheumatic basis. It should not be understood that these cases were treated simply by dietetic methods, for the skin, teeth, stomach, bowels, kidneys, and rectum each came in for their share of examination and treatment.—*International Medical Magazine.*

Acute General Peritonitis a Sequela of Measles.—Everett S. Hicks reports two cases of this rare complication. The first was a child of nine years who, on the third day of the measles, had a temperature of 105°, pulse 130. Fourth day, rash out and all symptoms better. Seventh day, patient complained of severe pain in region of umbilicus, headache and vomiting; temperature 102°, pulse 120. Abdominal muscles rigid, and tenderness general. In the second case, a child of four years, peritonitis appeared on the tenth day, with pain and tenderness, and temperature of 103°. Salines were used in the first case, and a rapid recovery followed. Salines were advised in the second case, but the treatment was not persisted in, and the bowels were kept confined for two weeks. (The author was called in consultation only in this case). The patient was in bed for a month, and was ill for three months.—*Annals of Gynecology and Pediatry.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 14, 1903.

INCREASE OF INSANITY IN GREAT BRITAIN.

STATISTICS dealing with mental disorders seem to show that undoubtedly these forms of disease have become more numerous within the past few decades. Perhaps the increase has not been so rapid as the figures appear to demonstrate, but at the same time it would be idle to argue that cases of insanity are not decidedly more frequent than formerly.

Mr. W. J. Corbett has been for many years a persistent contributor to the English *Westminster Gazette*, with the object of proving to the public that insanity has increased in the United Kingdom by leaps and bounds, and that the authorities have been attempting to hoodwink the people as to this fact. According to the *Fortnightly Review* of 1884, the registered number of lunatics in England was 36,762; in 1884 this number had risen to 76,765; while a later issue of the same journal showed that in 1901 there were no less than 110,713 lunatics in England.

Mr. Corbett, referring to what he terms the inability of alienists permanently to cure mental disorders, says: "While specialists in zymotic diseases have rendered signal service to mankind, the alienist alone has, so far, failed to make any appreciable progress in his own specialty; at all events, as results prove, he has failed to arrive at any discovery tending to lessen the spread of lunacy. From year to year, from decade to decade, from generation to generation, in spite of every effort made to stop the ravages of the disease, the insane continue to increase in great numbers—the leaven spreads annually with cumulative force, apparently under the influence of the natural law of reproduction, and the question has to be faced, How long will it take before the whole mass is leavened?"

Without admitting the truth of the writer's contention, that insanity cannot be treated successfully by present-day methods, one must acknowledge that it is a rare event for a lunatic to be permanently cured. Of course the treatment of the insane is conducted upon far more intelligent and humane lines than was the case fifty years ago. They are well housed, well fed, and used with kindness. Nevertheless, insanity increases, and, if we may believe Mr. Corbett, is spreading in Great Britain with alarming rapidity.

What then is the remedy? He argues that, cure being impossible, a policy of prevention should be pursued, and that, in place of erecting magnificent buildings in which the patients are pampered and coddled, an endeavor should be made to prevent the union of individuals with the taint of insanity, and to put forth vigorous efforts to improve the human breed in every way possible. Darwin, in the "Descent of Man," more than hinted at his belief that insanity was hereditary, while Francis Galton has stated plainly his views in the following words: "It is too certain that insanity and deteriorated mental powers likewise run in the same families."

With regard to means of prevention, Mr. Corbett quotes an American writer, Dr. Godsell, who says, in his Introduction to Clinical Gynecology: "I frankly confess that, in order to stamp out insanity, I am strongly inclined to advocate the legal sterilization of every man and woman who is the unfortunate victim of this hereditary curse." Again, Mr. Arnold White, in the *National Review*, suggested some time ago the following plan as a means of arresting "the propagation of the unfit." His proposal was to "extirpate them, by immuring them for life, not because they are wicked, but because their stock is corrupt," and he proceded to lay down this broad general principal: "If we are to become a healthy people, the permanent segregation of habitual criminals, paupers, drunkards, maniacs, and tramps must be deliberately undertaken."

This question has been discussed in America widely and often. Some States have gone so far as to favor the legalizing of measures by which persons would not be permitted to marry until they had undergone a strict medical examination, in order to prove that they were sound, and especially to show that they were not suffering from syphilis. However, such a scheme does not come within the range of practical politics, besides being an invasion of the rights of a citizen of a free country. It would surely be for the good of the communtiy at large if syphilitics, consumptives, maniacs, and habitual drunkards could be prevented from propagating a contaminated stock, but how to effect this object is at present not clear. The only remedy that Mr. Corbett can suggest is to have an international conference of qualified persons to consider the matter.

It would be interesting to gather statistics as to insanity from the whole of the United States, to compare with those of Great Britain, and to ascertain if lunacy is on the increase here, and, if so, to what extent.

HOSPITAL FOR TUBERCULOSIS IN NEW YORK CITY.

THE fight against disease is being waged in all parts of the world with increasing vigor. Scarcely a day passes but the news comes from one or another part of the globe that large sums have been provided, either by Governments or by private individuals, for the purpose of scientific research. Sanatoriums and hospitals have been given with a lavish hand. Of all the maladies to which the human race is subject, tuberculosis seems by common consent to take the first place. It probably kills more persons than any other disease, and is besides preventable and, under certain conditions, curable.

Recently, in both Great Britain and America, very large amounts of money have been donated by rich men, to aid in the efforts of medical men

to prevent, and if possible to extirpate, pulmonary tuberculosis. Sir Ernest Cassel in England a year ago presented $1,000,000 for the erection of sanatoriums for consumptives, and for research work in tuberculosis. Mr. Phipps a few weeks ago gave a larger sum for similar objects to Philadelphia, and now Mr. Rockefeller has placed at the disposal of Chicago University a still larger amount of money, to be devoted to the study of contagious diseases, especially of tuberculosis.

These gifts to other cities give rise to a sentiment somewhat akin to envy in the breasts of New York physicians. They cannot but feel that New York—of all cities in the United States most in need of the sinues of war with which to carry on a crusade against tuberculosis—has been left in the cold both by its municipal government and by its wealthy citizens. Dr. Henry P. Loomis voiced the sentiments of the medical profession of New York when, on Thursday evening, January 29, at the Pro-Cathedral, Stanton street, he urged the paramount necessity of the city government establishing a large and completely equipped hospital for the accommodation and treatment of tuberculosis and other lung troubles. As a matter of fact, not only is New York inadequately provided with facilities for caring for its consumptives, but in this respect is worse off to-day than it was ten years ago, for the reason that those suffering from tuberculosis are now, owing to the fear of spreading infection, barred from the general wards of city hospitals.

It is estimated that there are 30,000 persons suffering from consumption in New York, the majority of whom live in the overcrowded districts of the city, where their presence is a menace to their neighbors.

Dr. Loomis is of the opinion that there are only two ways known of reducing the mortality from tuberculosis: "First—by preventing its spread by direct infection. Second—by educating the people to the importance of taking care of themselves when the disease first commences. He thinks that a large and thoroughly equipped consumption hospital should be erected on Blackwell's Island, and that this building should be large enough to accommodate all those in an advanced stage of tuberculosis. In connection with this main hospital an annex should be built in the country near New York, and should be used for the accommodation of those in the early stages of the disease.

The MEDICAL RECORD during the past three years has strongly advocated that adequate means should be provided for the care of the indigent consumptives of New York. Other cities far less rich than New York have exhibited greater humanity toward their poor consumptives, and it is a slur upon the city government that these unfortunates are left to die without proper help, and to some extent to act as a foci of infection. Such a policy is short-sighted and inhuman.

TREATMENT BY FINSEN LIGHT.

TREATMENT by chemical rays has not as yet made so great progress in the United States as in some of the European countries. The therapeutic effects of the violet and ultra-violet rays have been shown to be remarkable, and in France, perhaps, this form of treatment has reached the highest stage of development.

In *McClure's Magazine* for February are descriptions of the origin and rise of phototherapy, together with a sketch of Niels Finsen, its discoverer.

It was in 1893, according to Cleveland Moffett—after having experimented for some time, and after having practically demonstrated the efficacy of red light in preventing scarring from smallpox—that Finsen set himself the task of investigating the bactericidal action of the blue, the violet, and ultra-violet rays. He first showed that the green, yellow, and red rays are practically useless as bactericidal agents, and then found out that while unfocused sunlight from a midsummer sun had a limited destructive action upon bacteria, that these same bacteria were destroyed almost instantly when exposed to concentrated actinic rays. His experiments further proved that powerful electric light is more efficacious in destroying bacteria than ordinary sunlight, as the latter, however, concentrated, looses part of its ultra-violet rays in passing through the earth's atmosphere, while the former possesses these in abundance. It was also discovered that the penetrating properties of the actinic rays upon the tissues are greatly enhanced when the circulation of the blood has been arrested and temporary anæmia has been produced, as the red color of the blood acts like red glass in opposing the passage of any light but red.

Lupus was the first disease upon which Finsen tested the bactericidal action of the ultra-violet rays, and the success of his experiments is now a matter of history. The fact was at once recognized that a most important medical discovery had been made. The establishment of the Finsen Light Institution in Copenhagen was the first fruits of this discovery, followed by the installation of apparatus designed to use the actinic rays to the best possible advantage, in every civilized land.

At the London Hospital, in the East End of London, the largest hospital in the united Kingdom, and situated in the midst of the most poverty-stricken part of the British metropolis, a Finsen-light Department has been established. Since the installation, in the spring of 1900, 398 patients have been treated at the London Hospital, of whom 149 were discharged as completely cured, and 232 are at the present time under treatment. Lamps for the treatment have been installed at the Charing Cross and Westminster hospitals, as well as at Liverpool, Manchester, Dublin, and at various other of the provincial hospitals of Great Britain.

With regard to the Finsen system in America—as remarked before—its progress has been somewhat slow. Dr. George G. Hopkins, who writes on this phase of the matter in *McClure's Magazine*, attributes this tardiness on the part of American medical men to make their countrymen participators in the benefits of the Finsen-light treatment to the following reasons: "First, the established conservatism and distrust of new methods characteristic of the medical profession of this country, which has kept the Finsen system out of our hospitals; second, the considerable expense of instalment and maintenance which puts the matter beyond the reach of many practitioners; and, third, the rarity of lupus." Whatever, however, may be the reasons, it is assuredly the truth that American

European institutions—in their practical appreciation of the efficacy of the light treatment. There are, nevertheless, many private practitioners who have eagerly availed themselves of the road opened to them by the genius of Finsen, and, furthermore, have had much success with the Finsen ray, and this ray in conjunction with the *x*-ray in the treatment of various forms of skin diseases, and even of superficial cancer.

The time is yet young to speak definitely of the future of the actinic rays as a therapeutic agent in many diseases. But, so far as can be judged from the results up to the present time, the discovery of Finsen bids fair to take rank with the most valuable medical discoveries of this or of any age.

Subway and Crowded Car Ventilation.

In immense cities, such as London and New York, the transportation of the inhabitants presents a problem of almost insuperable difficulties. In London subways and deep tunnels have been resorted to as almost the only way of successfully grappling with the situation, and New York is, to some extent, following suit. But subways and deep tunnels, although they may relieve the congested service traffic, are by no means unmitigated blessings. Dr. Sutherland has recently made analyses of the air of the London "tubes," with the result that while air taken at the street level outside the stations of the Central London Railway contained an average of 2.83 parts of carbon dioxide per 10,000, tests of air taken at the same time from the interior of the stations, and from the cars within the tubes, showed that on the station platforms the percentage varied from 4.23 to 7.36 parts during the hours of moderate traffic and during the busiest hours the percentage rose from 11.04 parts to 20.46 parts per 10,000. Such a percentage of carbondioxide is in a high degree unhealthy to a strong person, while a much less percentage cannot be but injurious to an individual of weakly constitution.

The *Scientific American*, January 24, points out that soon there will be both deep level tunnels and subways in New York City, and that therefore the question will become one of the most vital moment to the New York traveling public. The above-named journal says that "it is at present rumored that the subway engineers are trusting to the movement of trains to produce sufficient ventilation, and if so, it looks as though they were confusing ventilation and circulation. The movement of trains will produce circulation, but if the air be already vitiated, it will require something more than the mere transfer of the air by the piston-like action of trains to render it pure. Provision must be made for taking into the tunnels a supply of fresh air and expelling that which has been vitiated, and to secure the best results, the action should be constant and not intermittent."

The Merritt Bill and the Superintendent of Public Instruction.

The medical profession is much interested in the "Merritt bill," and naturally so. This measure proposes to place in the hands of the State Superintendent of Public Instruction such moneys as the Legislature may appropriate to pay for the tuition in high schools of such children as can find no high-school accommodations in their own school districts and are desirous of continuing beyond the grade schools. Governor Odell has recommended such an appropriation by the Legislature, and all educators and sociologists are favorable to the proposition. Who shall administer this fund? Such is the issue raised by the Merritt bill, because the author of that measure would make the innovation of having the State Superintendent of Public Instruction act as the disbursor of these moneys. Educators throughout the State are opposed to such a dispensation. They demand that the mentors of the common schools remain in their own sphere of action, and leave to the Regents the care and management of all matters pertaining to secondary or higher schools. It is true that under a law passed in 1895 the Legislature did enact that the Superintendent of Public Instruction might approve courses of study in secondary schools to satisfy himself that the standards of study were sufficient for teachers under his care, but the fact remains that the Regents are and have been held responsible for the rank and standing of all high schools and academies in the State, and any attempt to alter their control of these institutions will be deemed an attack on a system of which all professional men, and especially physicians, are proud. To use a homely expression, symbolic of school-boy days, we would advise the State Board of Public Instruction to "shinny on its own side." We want no innovations in our system of secondary education, but we do want a continuance of our splendid Regents' management, which has made us the envy of our sister States because of the advances in professional standards which have been made by reason of the excellence of Regents' methods. Every three years there is likely to be a change in the personnel and in the policy of the Department of Public Instruction. Education, pure and simple, is the factor controlling the policy of the Regents' office, and the executive of that body and all of his subordinates are appointed solely because of comparative merit. The policy of the Regents' office is one of progress in education and advancement in standards, regardless of the party which controls the political situation. Therefore, it is that the medical profession of New York State, jealous of its laurels gained through coöperation with the Regents' office, calls to its legislators: "Hands off the secondary schools! Let the Regents administer for their own!"

Cremation.

Cremation within the past few years has made much progress in Europe, and still greater progress in the United States. San Francisco at the present time leads the world in the number of its citizens who are yearly cremated. Despite, however, that more persons are, year by year, subjected to this process, there still exists much prejudice against cremation among the population at large.

In *Municipal Affairs*, January, Louis Windmüller writes a strong article, advocating cremation as a healthful mode of disposing of the dead. He says "In a modern crematory the unclad corpse, simply wrapped in a damp winding sheet, is noiselessly rolled to the retort, and quickly consumed by air that has been heated to 1,500° F. Gases are consumed in the same furnace in which the body is burned, so that it may not offend the nostrils of the most sceptical critic. Some crematories have been erected in the very heart of modern cities, and would draw no attention, but for the peculiar construction of the edifice . . . Cremation merely reaches, in a shorter period the same final result as burial. Fleshy parts of the corpse decompose in the earth in five or ten years; during the whole period

of decomposition they constitute nothing but a putrid mass of carrion. Bones, which take centuries to crumble, are unceremoniously carted from one cemetery to another when necessity compels their removal, and increase the horror of death after they have ceased to be identified and claimed. If they are converted, with the flesh, into ashes in an hour, they are insured against desecration. The volume and weight of bodies are reduced by the process of cremation some 95 per cent."

Mr. Windmüller ends as follows, "Considering the marvellous progress we have made in every other direction, it is strange that we have failed to adopt the most rational means for the deposition of dead bodies. We hardly are abreast of Homer's contemporaries, who realized that, however well a cemetery may be managed, corpses can do harm, but ashes never can."

The most forcible argument that can be urged in favor of cremation, is that no danger to health can happen to the community from the process. In these times of over-crowded cities, grave-yards in our midst, and cemeteries in our immediate neighborhood are, to say the least, unhygienic. The other objections to cremation are chiefly of a sentimental nature, and will not stand the battery of sound common sense.

Becquerel Rays.

Since the discovery of the Röntgen rays, various observers have been making investigations into the subject of radiation. The fact that the *x*-rays produced phosphorescence when they fell on sensitive substances, directed attention to the phosphorescence spontaneously emitted by the salts of uranium and substances of a like nature. It was thought that the phosphorescence of the Röntgen rays might be due to the uranium present.

Joseph John Thomson, P.D.S.C., F.R.S., Cavendish Professor of Experimental Physics, Cambridge, England, writes on the matter in *Harper's Magazine*, January. He says, in part, "The subject was taken up by Professor Becquerel of Paris. He took a quantity of salt of uranium, and placing it near a photographic plate protected from light by light-proof screens, kept the uranium in a state of phosphorescence by continued exposure to sunlight. On developing the plate after the experiment had lasted several hours, he found a picture upon it, showing that something similar to Röntgen rays had been given out by the uranium. In all the earlier experiments the uranium was kept exposed to the sunlight, and was thus phosphorescing during the whole time of exposure. It happened, however, one day, that after Becquerel had prepared his uranium and photographic plates, and exposed them to the sun, the sky, after a short time, became clouded over, and there was not light enough to make the uranium phosphoresce. Becquerel put his apparatus away in a drawer, and waited for better weather. The weather, however, did not improve, so that after waiting for some days, Becquerel developed the plate, expecting, as the uranium had been phosphorescing for so very much shorter time than in the earlier experiments, to get, if he got anything at all, an exceedingly faint picture. To his surprise, he found that the picture excelled all those he had previously taken." By further experiments, Becquerel established the fact that the emission of the radiation is a property of the uranium itself, and is not dependent upon any previous stimulation.

The Becquerel rays, so named from their discoverer, are very similar in their action to Röntgen rays, and are, indeed, a mixture of these rays and cathode rays. M. and Mme. Currie have continued researches with regard to uranium radiation, and have found out some very interesting points. Professors Rutherford and Soddy of Montreal have also investigated the matter of radiation from uranium, and obtained valuable results.

Professor Thomson finally concludes that all objects on the surface of the earth, which are radioactive, are cathodes, discharging cathode rays into the air, and that cathode rays are omnipresent on the earth surface.

The discovery of the Röntgen rays has given an immense impulse to investigations into the properties of light and radiation. The subject is, as yet, in its infancy, but judging from the good effects of the light treatment of certain diseases, it may not be too much to hope, that with greater knowledge of radiation, there will be corresponding progress in this mode of treatment.

The Large Intestine Regarded as a Syphon.

Dr. R. W. Leftwich, writing in the *Edinburgh Medical Journal* for December, states his opinion that the ordinarily accepted view, that the large intestine and particularly the ascending colon does its work by peristaltic action, is not borne out by the anatomy of the latter organ. He believes that the large intestine acts on its contents by syphonage.

"The large intestine," says the writer, "has a remarkable resemblance to a syphon. A syphon consists of a reservoir, a short ascending tube, and a long descending one. So does the large intestine. The reservoir, in this case closed, though compressible, is the cæcum; the short ascending tube, 8 in. long is the ascending colon; while the long descending tube consists of the descending colon, 8½ in. long, and the rectum about 7½ in.; the total length being, therefore, about double that of the short tube, and likely to act as a very efficient syphon."

By experiment Dr. Leftwich convinced himself that a syphon can act, although its contents are partly fluid and partly gaseous, and from further experiments he concluded that in all essential respects the large intestine was qualified to fulfil the functions of a syphon.

The argument as to the manner of working of the large intestine, considered as a syphon, is thus described: "The point in a syphon which it is necessary for the descending current to pass in order to start the flow, when the short tube is full, may be conveniently termed the balance point. The balance point in the bowel is the sigmoid flexure. The following is the cycle of events in health: After the partial evacuation of the large bowel, consequent upon defecation, all syphonage is stopped, the vacuum is broken, and the cæcum and colon slowly fill again. The following morning meal increases both the peristalsis and the intraintestinal pressure, and there soon comes a time when the fæces are pushed past the balance point, and syphonage takes place. The rectum and its pouch are filled, and the cæcum emptied. Should the contents of the bowel be very liquid, the quantity may be so large that the syphon endeavors to work after the rectum is filled, and then the sphincter being unable to resist such pressure for long, the hint to defecate becomes a command. But, in general, the fæces are more or less clayey, and the syphonage more deliberate. Thus the contents of the cæcum are transferred to the ascending colon, while those of the sigmoid flexure are transferred to the rectum. Voluntary defecation is accomplished by reducing the cubical capacity of the abdominal cavity. The diaphragm is made to descend by an inspiration, and is fixed in that position by the closure of the glottis. This

gives a rigid roof to the cavity. The levator ani in contracting encroaches upon the pelvic cavity. This forms a rigid floor. Then the abdominal muscles contract, and so compresses the sides of the abdominal cavity, that the contents of the rectum, aided by the contraction of its muscular walls, follow the path of least resistance and escape from the anus. The collection in the rectal pouch is that most susceptible to pressure and escapes first; there is then a pause, during which the pouch is again filled up from the rectum; another voluntary effort evacuates the second collection, and, perhaps, a third or fourth effort may be necessary; and, after all, some fæces may be left in the cylindrical portion of the rectum, which, indeed, is not very susceptible to pressure from voluntary effort. The expression 'the bowels have been emptied' must not be taken literally. The volume of an ordinary stool is very small compared with that of the contents of the entire large intestine; the bowel, therefore, is practically left full to within a short distance of the 'balance point.' Thereafter the cæcum slowly fills again till the bottom of the column on the left side is once more pushed past the balance point, when syphonage recommences, and the other steps follow. In diarrhœa the time occupied by the refilling may be very short, and the syphon action recurs at very frequent intervals. The time is prolonged in health by the concurrent absorption that takes place."

According to Doctor Leftwich's theory, syphonage explains the customary single evacuation a day. With a continuous flow, and no sphincter above the rectum, one would expect frequent evacuation, and this is the case in such quadrupeds as maintain the horizontal position of the trunk at all times.

The suggestion of the author is, therefore, that the force used to move the column of fæces and start the flush is hydraulic. We have, he says, a small cylinder, the ileum; a large cylinder, the cæco-colon; and a piston, the column of fæces, inseparable, albeit, from the body to be moved. The difference in the sectional areas will represent a multiplication of the power by six. The article concludes by saying that definite functions have now been assigned to the rectal pouch, the sigmoid flexure, the great arch of the colon, the cæcum, and the intestinal gas.

The explanation given by Doctor Leftwich of the mode in which the great intestine performs its duties is at least plausible, although contrary to preconceived notions. Perhaps the strongest point to be urged in its favor is that animals which maintain a horizontal position defecate frequently. If further investigation into the matter tends to confirm Doctor Leftwich's views, the road will be opened for fresh ideas as to treatment. It would be interesting to learn the habits of the monkey tribe with regard to defecation, as this class of animals, on the whole, most closely resemble the human species in manner of ordinary posture.

The Menace of New Orleans.

According to the *New Orleans Medical and Surgical Journal*, the streets of that city were never dirtier than they are at the present time, and the authorities seem to be absolutely indifferent to their condition. Filth of all kinds is accasionally scraped out of the gutters and collected in piles in the streets, and then is blown about as dust or oozes back into the gutters when it rains. "The main thoroughfares," says our contemporary, "usually the pride of urban communities, are so covered with accumulated mud and dirt as to invoke comment at strangers' hands. The City Board of Health is trying to do its best along its own lines, and it has met adverse criticism because of the attack upon the present method, or lack of method, in garbage disposal. We have already become a great convention city, but our streets and conditions of hygiene in those regards are not of the sort just now to command the highest regard or praise from transient guests. There must be some reason and also some remedy."

If the city authorities are so indifferent, cannot the State Board of Health do something? Of what use to insist upon strict quarantine, which experience has shown repeatedly cannot ever be absolute, when all the conditions in the city, with its countless breeding-places for the yellow-fever mosquito, invite to an epidemic of that disease? The city is a menace to the country. Its authorities should take a lesson from Havana, and learn to trust more to internal cleanliness than to the frail and permeable barriers of quarantine. The medical officers of the United States Army have shown the way of preservation from yellow fever, and the boards of health of our southern cities and States can do no better than to follow the lead which has been shown them. Academic discussion is interesting, and no one would suppress it, but in the presence of danger what is demanded is action, speedy action, and action that has been amply demonstrated to be effective. Summer is close at hand.

News of the Week.

The Bellevue Hospital Alumni Association.—The annual dinner of this association was held at Delmonico's on February 4. Speeches were made by Mr. Homer Folks and Drs. John W. Brannan, A. Alexander Smith, D. B. St. John Roosa, and Ramón Guitéras. In the course of the evening a presentation of silver was made to Dr. J. W. S. Gouley in commemoration of his fifty years of service as an attending physician at Bellevue. Dr. Brannan, President of the Board of Trustees of Bellevue and allied hospitals, in the course of his speech made the welcome announcement that plans are on foot for a new building for Bellevue Hospital, which will take about five years for completion and will cost in the neighborhood of $3,000,000. He spoke also of other important changes accomplished or projected, such as improvement in the insane pavilion, under which Bellevue patients now received the same treatment as that administered at the State hospitals; of the organization of a fire brigade, with frequent and regular drills, and of changes in the house staff. He also spoke of the newspaper charges against nurses and attendants in the alcoholic ward of the hospital. These, he maintained, were absurd in their nature and utterly unfounded.

Report of the New York State Board of Health.—The annual bulletin of vital statistics for 1902, recently issued by the State Department of Health, shows that there were 124,160 deaths during the year, making a death rate of 17 per thousand population. The number of deaths was that of the average of five preceding years, and about five thousand less than the mortality of 1901. The decrease from last year was in all the sanitary districts. It occurred mostly in the winter months. The midsummer mortality last year was unusually low. The infant mortality was almost 5,000 less than the average. This decrease was in the autumn, in rural parts of the State. One-fourth of the deaths occurred in children under five years old; deaths of

persons more than seventy years old ranged from 10 per cent. of the total in the maritime to 30 per cent. in the central districts. There were 8,800 deaths from pneumonia, and about 5,500 from Bright's disease. The acute respiratory mortality was a little below the average. Influenza was estimated to cause 4,000 deaths in the early months of the year. Its annual recurrence in November and December was moderate, causing probably not more than 500 deaths.

Eating on the Run.—Our venerable contemporary, the *Lancet*, is alarmed by the report that the so-called American "quick-lunch" system is about to be introduced in London. In terror and dismay it urges its readers "to impress upon their patients that the adoption of this proposal would be a wicked physiological step. The demands of business may be pressing, but the demands of the body are a reality, and are more serious." Indeed they are, but the imagination of the American correspondent who dishes up horrors for the timid Britain to breakfast upon must have its playful way as well.

Anti-Tobacco Legislation.—The Nebraska State Board of Health recently passed resolutions commending a bill, now before the Legislature of that State, which provides "that no minor under the age of eighteen years shall smoke or in any way use any cigarettes, cigars, or tobacco in any form whatsoever, in any house, place, highway, street, square, or resort. Any minor violating the provisions of this act shall, upon conviction be fined in any sum not less than $1 or more than $10, or be imprisoned for two days for each offense, in the discretion of the court."

A New Italian Dispensary.—The McKinley Dispensary of New York City has made application to the State Board of Charities for incorporation. It is organized to maintain a dispensary especially for persons of Italian origin. The directors are John A. Price, Max Ghertler, E. K. Bowd, Michaele Viccali, and Marcus Schnitzer of New York City.

Increased Powers Asked for the State Board of Health.—A bill to increase the powers and prerogatives of the New York State Board of Health has been troduced into the Legislature. It requires water supply, sewage, etc., in works built by or for the State to be approved by the State Health Commissioner. It permits the State board to appoint local health officers upon nomination of local boards, and provides for extra pay in cases of epidemics, etc. It requires villages to improve their sanitary facilities upon order of the State Health Department, if necessary, by extra taxation or loans, and to enforce general vaccination upon the State board's order.

The Plague.—Wisdom is breaking upon the business men of San Francisco, who are learning that their policy of concealment is having a contrary effect to what they fondly hoped. A joint committee representing various boards of trade and merchants' associations has adopted a set of resolutions addressed to the Governor of California and the municipal authorities of San Francisco, urging them to coöperate with the United States Marine Hospital Service "to the end that all danger from bubonic plague may be eradicated, that all fears of infection may be removed, that the confidence of the boards of health of other States and Territories may be restored, and that no injury, however remote, may result to the foreign and interstate commerce." The energetic measures adopted by the Mexicana National Board of Health and the local authorities are having their effect in a noticeable abatement of the plague epidemic at Mazatlan United States Consul Kaiser of that city has advised the State Department in Washington that the total number of deaths from plague up to February 1 was 200, and the total number of cases to the same date was 260.

An Emergency Hospital Car.—The Erie Railroad Company has converted a combination baggage and smoking car into a hospital, for use in case of wrecks in which anybody is injured. Six single cots, with woven wire springs and hair mattresses, have been placed in the large compartment and the baggage room has been fitted up with an operating table and the necessary sterilizing apparatus. The company has in course of construction a specially designed hospital car, which, when completed, will be substituted for the temporary ambulance now in use.

Typhoid Fever was never apparently more widely prevalent in this country than it has been and still is this winter. It is epidemic in nearly every large city in the country, Chicago and Philadelphia enjoying their usual proud preëminence as leaders in this respect. In Ithaca there have been over three hundred cases, the epidemic being readily traceable to the impurity of the water supply. Many of the sufferers are students of Cornell University, some of whom have died. The Cornell infirmary can accommodate no more patients, but the university authorities are fitting up rooms in private houses near the hospital, and hope thus, by concentrating the cases, to properly care for all with the available number of physicians. Many students have left the town for fear of the fever. The situation in Cleveland is beginning to cause alarm. The number of cases has increased steadily during the past few weeks, and the hospital accommodations are taxed to their utmost.

Reopening of a Hospital.—The Williamsburg Hospital at Bedford avenue and South Third street, which was closed last month for lack of funds, will probably reopen, as sufficient funds have been secured to cover the greater part of the deficit of last year.

A Legislative Clinic.—There is a bill before the New York Legislature providing for the appointment of a State board of examiners to inspect the condition of barber-shops and to enforce the sanitary regulations. In support of this bill, several members of the Assembly, who are suffering from barbers' itch, appeared before the General Laws Committee, which has the measure under consideration, as living exhibits of the dangers of even well-appointed and seemingly clean barber-shops where the necessary sanitary measures are not strictly enforced.

The Rockefeller Laboratory.—It is reported that a tract of land covering several city blocks on the east side of the town near Eightieth street has been bought for the Rockefeller Laboratory for Medical Research. The land is reported to have cost about $750,000 and the buildings will probably cost half a million more. As soon as all the formalities of the purchase are completed the location and plans will be made public.

Medical Practice in Spain.—Since 1868, foreign practitioners desirous of exercising their calling in Spain have been accorded very great facilities, the recognition of equivalence and the grant of the right to practise having been left in the hands of the medical faculties. This latitude, it seems, has given rise to considerable abuse, at any rate that is the reason alleged by the Government for withdrawing the right of granting dispensations and permits from the universities and vesting them in the State. All existing licenses to practise granted to persons not possessed of a Spanish diploma will be held to have expired six years hence, dating from November 9,

1902. In future only temporary permits will be conceded, and these only at the instance of the Government and with the approval of the General Council of Education.—*The Medical Press and Circular.*

Smallpox Hospitals.—A new smallpox Hospital in Rochester N. Y., built at a cost of $40,000, was opened for the reception of patients on February 7. The epidemic in the city is believed to be over, there now being only thirty-three cases left in the old Hope Hospital. At one time more than 200 cases were there, being cared for in city election booths. A hospital for smallpox sufferers is to be built soon in Washington, the House District of Columbia Committee having recommended an appropriation of $25,000 for this purpose.

Philadelphia Neurological Society.—At a stated meeting, held January 27, Dr. D. J. McCarthy demonstrated a new spinomuscular phenomenon, which consisted in contraction of the adductor tendons of the thighs when the finger of one hand used as a plexímeter, and applied to the lumbar spine, is struck with percussion hammer. Dr. McCarthy demonstrated also some new pelvic reflexes. These consisted in contraction of the adductor muscles of the thigh when their tendinous attachment to the pubic bone was struck with a percussion hammer, and a similar contraction of the sartorious under the same conditions. Dr. W. G. Spiller spoke of paradoxical reactions of the pupils, such as dilatation on distant vision and contraction on distant vision, and dilatation on looking inward and downward. Drs. C. W. Burt and D. J. McCarthy presented a communication entitled "Two Cases of Huntingdon's Chorea, wirh a Report of the Pathological Examination in a Case." The cases reported were typical, and occurred in father and son, three other sons also being affected. In the case examined histologically hemorrhages and infiltrations were found in various parts of the brain, together with internal hydrocephalus. Dr. Wilfred W. Hawke exhibited a case of hemiplegia with sweating on the palsied side of the head and the opposite shoulder. The patient had had several appoplectic attacks in the course of some ten years, and he presented right hemiplegia without aphasia, with contractures, exaggeration reflexes, widening of the palpebral fissure and dilation of the pupil on the right, sweating on the right side of the head and face and the left shoulder and without other symptoms of aneurysm or neoplasm. Drs. Wm. J. Taylor and Wm G. Spiller reported a case of multiple fibromata confined to the internal plantar nerve. Pain and nodules developed in the sequence of traumatism, and several operations were required in the course of fourteen years to get rid of the constantly recurring formations and to free the patient from her symptoms. Drs. L. Pierce Clark and Thomas F. Prout presented a communication entitled "The Histopathological Changes in the Cerebral Cortex of Epileptics and Their Interpretation, with Demonstration of the Lesion." Examinations made in a number of cases dying in the epileptic status were made shortly after death and degenerative changes found in the cells of the second layer of the cortex at almost all points. The disease was considered a sensory disorder, the attacks being excited through impulses conveyed by way of afferent nerves, the underlying condition being one of instability of the nervous system, inherited or acquired, and the determining factors irritants of various kinds generated within the body or introduced from without. The following officers were elected for the ensuing year: *President*, Dr. H. A. Hare; *Vice-Presidents*, Drs. Jos. Sailer and D. J. McCarthy; *Secretary*, Dr. A. A. Eshner; *Treasurer*, Dr. Guy Hinsdale; *Councillors*. Drs. C. W. Burr, C. S. Potts, and W. G. Spiller.

Obituary Notes.—Dr. Eugene Foster of Augusta, Ga., died on January 23, of cancer of the stomach, at the age of fifty-three years. He was a graduate of the Medical College of Augusta in the class of 1872, and at the time of his death was professor of the practice of medicine and of sanitary science and dean of the medical faculty at the University of Georgia. He was especially interested in matters of public health, and was a recognized authority in sanitary science. For twenty-five years he served as president of the Augusta Board of Health, and he was a prominent member of the American Public Health Association. He was also a member of the American Surgical Association, of the New York Medico-Legal Society, of the Richmond County (Ga.) Medical Society, of the Georgia State Medical Society, of which he was president in 1885, and of the American Medical Association.

Dr. Earle Eugene Woolworth of Brooklyn died on February 5 from cerebral injuries received in being thrown from a carriage two weeks before. He was born in Lyonsdale, N. Y., thirty years ago. and was graduated from the New York University Medical School in 1897. He was a member of the Alumni Association of the City (Charity) Hospital, of the Kings County (N. Y.) Medical Society, and of the New York State Medical Association.

Dr. J. Frank Valentine died on February 5 at his home in Richmond Hill, Queens Borough, from typhoid fever. He was born in this city in 1856, and was graduated from the College of Physicians and Surgeons in 1879. For many years he was a visiting surgeon at St. Catharine's Hospital, Brooklyn. He also served as surgeon of the old Thirty-second Regiment, and for several years was Coroner's Physician in Brooklyn. He became chief surgeon of the Long Island Railroad in 1890, and also acted as visiting surgeon at St. John's Hospital, Long Island City, and as consulting surgeon to the Nassau Hospital, at Mineola, L. I. Dr. Valentine was a member of the Queens-Nassau Medical Society, and an ex-President of the New York State Association of Railway Surgeons.

Dr. Henry W. Allan of Brooklyn died on February 5, at the age of forty-two years. He was a graduate of Bellevue Hospital Medical College in the class of 1882, and had practised medicine in Brooklyn for about five years.

Dr. Herman Mynter died at his home in Buffalo, N. Y., on February 9. He was born in Denmark in 1848, and was graduated from the University of Copenhagen in 1871. He had lived for many years in Buffalo and was one of the leading practitioners in the western part of the State. He was one of the surgeons in attendance upon President McKinley when he was shot by the assassin at the Pan-American Exposition in September, 1901.

Dr. Thomas N. DeBowes died at his home in Brooklyn on February 7. He was born seventy-one years ago in Ireland and was a graduate of the University of Dublin. He came to this country when quite a young man, and was graduated in medicine from the New York University in the class of 1858. During the Civil War he served as a surgeon in a regiment of Connecticut Volunteers. For many years he was a coroner's physician in this borough. He was one of the founders of St. Mary's Hospital in Brooklyn.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BART'S—LORENZ'S DEMONSTRATION—PYLORIC STENOSIS—HEMORRHAGIC TYPHOID FEVER—STEPHEN COLERIDGE AGAIN—SIR M. FOSTER—LONDON UNIVERSITY LIBRARY—SIR W. TURNER—EDINBURGH UNIVERSITY—DR. CLOUSTON—QUALIFIED NURSES.

LONDON, January 23, 1903.

THE Lord Mayor presided over the Mansion House meeting on Monday of the Special Committee of Governors of St. Bartholomew's Hospital. This meeting appointed a a committee of fifteen members, nine to be nominated by the Lord Mayor and six by the treasurer of the hospital (Sir Trevor Lawrence), the two nominators to be *ex-officio* members, to report as to whether it is desirable to retain the hospital on its present site, and if so, whether a better scheme of rebuilding than that proposed can be devised. Further the committee may report on any other matters affecting the hospital which they may think it desirable to inquire into.

Professor Lorenz has given his demonstration here. It is curious that his arrival was widely announced in the public press, and that with him the ubiquitous reporter should have attempted to follow the methods practised at Chicago. Perhaps curious is not the proper word. Either the professor or those who exploited his visit here must be held responsible for what occurred. His demonstration was given at a small special hospital in the city, where he was received by the staff, the senior member making a speech and the professor replying. This surgical discussion was reported in some of our more sensational papers—to the disgust of the general profession. It is asked who supplied the copy to these papers, and when reporters are blamed the question is followed up by who invited and who admitted reporters to an operating theater? Others asked did the professor exploit the staff or the staff the professor? The staff should try and clear themselves, unless they are contented to be regarded askance by their confrères.

English surgeons, and I doubt not Americans, also, know as much about congenital dislocations of the hip as Professor Lorenz, and they have given full recognition to his views. On the 9th of this month, at the Clinical Society, Mr. Openshaw, C.M.G., read a paper on the "Morbid Treatment of These Luxations," based on seventy cases, upon nine of which he had operated. He had always found that the acetabulum was small, shallow, rather triangular, and the cartilage forming its floor thickened. He thought the head of the femur remained normal up to about three years, and after that age became flattened and gradually disappeared. He had tried two operations: (1) reduction of shortening by tenotomy and extension and so-called reposition by manipulation, as practised by Lorenz; (2) remaking acetabulum by the open method after reposition had been made possible by the former proceeding.

As a result of about twenty cases treated by the first plan in the last five years, he considered reposition *within* the joint impossible and redislocation exceedingly common. Consequently he advocated a combination of the two methods. He said that shock was much less if the shortening was first overcome, and if any open operation were advisable the acetabulum ought to be deepened. In illustration of his views he showed two cases in which he had obtained excellent results. He also exhibited a specimen from a girl of five years who had died of pneumonia to show the condition of the parts at that age.

The President, Mr. Howard Marsh, directed attention to Mr. F. F. Burghard's paper in the *British Medical Journal* of 1891, in which were very exact anatomical investigations. Mr. Burghard referred to hour-glass contraction of the capsule, which was an obstacle to reduction, probably due to the iliopsoas tendon. The head of the femur was often found in an upper pouch of the capsule above the acetabulum and shut off from it. The President did not believe in simple extension, and thought the best result was often bony ankylosis. He remarked, too, that the subsequent history was often wanting, as in a young woman to whom he had been called and whose case had been widely reported as cured by long extension at the hands of a late well-known surgeon, but, as a matter of fact, it was obviously a case of unaltered, unreduced congenital dislocation.

Some of our practitioners are rather exercised in their minds about congenital hypertrophic stenosis of the pylorus, chiefly on account, perhaps, of a discussion which took place last month at the Medico-Chirurgical Society. The affection, whatever its nature, seems rare enough, only about twenty cases being recorded. It seems likely, however, that some deaths registered under such terms as atrophy, marasmus, etc., may have been due to this stenosis. The surgeons, therefore, are reckoning on a fresh triumph, successful operations having been performed, though they are not quite agreed as to the best procedure. One thing they are, as usual, unanimous in demanding, viz., early diagnosis. Some general practitioners are disposed to shake their heads at this, but on them and physician-accoucheurs would seem to rest the responsibility of calling in the surgeon. Others seem to think abdominal section in new-born babes rather a desperate remedy. Certainly if a few infants have died from unsuspected stenosis, it is also possible that a general knowledge of the occasional existence of such a condition might have led to a few unnecessary operations; for, at present, there are some who consider the affection to be secondary to spasm, a view which suggests that it might be amenable to treatment in the primary stage.

Hemorrhagic typhoid fever being rare and the symptoms for a time sometimes masked, diagnosis is difficult. Dr. Goodall related a case to the Clinical Society which occurred in a hospital nurse who, after being "out of sorts" for a week, noticed purpuric spots on her legs. Her temperature was then taken and found to be 104° F. In the next few days more purpuric and petechial spots appeared in the skin and subcutaneous tissue, and there was bleeding from the gums and fauces, with epistaxis. There were also hæmatemesis, hæmaturia, metrorrhagia, malæna, with continued pyrexia, but no rose spots and no splenic enlargement. The patient died a fortnight after the first spots appeared. The post mortem revealed typhoid ulceration. There were also hemorrhages into the stomach, peritoneum, bladder, and right kidney. In this last-named organ were small yellow spots, which were masses of round cells surrounding clumps of bacilli —probably bacilli coli. The blood gave a feeble serum reaction. The heart blood contained colon bacilli, and that from the spleen and a mesenteric gland gave colon and typhoid bacilli.

This case was first diagnosed as acute bacterial infection, perhaps streptococcal, but two or three days before death typhoid fever was suspected. Calcium chloride and adrenalin were tried without effect. A little discussion ensued, in which it was stated that such cases were mostly met in confirmed alcoholics, and Dr. Wright lately stated that alcohol diminished the tendency to coagulation of the blood. In this case Dr. Goodall said alcohol could be excluded, and it was not given medicinally until late in the case. It was the only marked case of the kind in a series of 1,733 cases of typhoid fever.

Mr. Stephen Coleridge takes the opportunity of the London Hospitals' quinquennal appeal to write again to the papers that, in his opinion, it is a misappropriation of the funds to give any to the school. He has been told before that to dispense with the services of the school would entail expenses fully seven times as great, and in spite of his ridiculous assertions the governors have found it a good investment. He wants the school to furnish him, as standing counsel for the Antivivisectionist Society, with detailed accounts, and the hospital too. He is now told that he has no right to ask, as he has never subscribed a farthing. But he does not like to be snubbed, and so returns to the charge with the pretense that as the students are learning their profession their services have no pecuniary value to the hospital. He knows quite well that those who have learned and are qualified, in considerable numbers, give their services, and if there were no school attached they would have to be paid. But it is useless to argue. If it be true that a counsel is paid to "make the worse appear the better cause;" his advocacy of the antis may be worth all they choose to pay him.

Sir Michael Foster, with the help of a post-card plebiscite of his supporters in the constituency conducted by his committee, has at length been enabled to make up his mind, and will retain his seat for the London University. It is frequently remarked that his vacillation is not a recommendation of scientific candidates for the House of Commons.

Convocation of this university has urged better treatment for its library. It was said at the meeting that the books had not been arranged since the removal two years ago, and a number are certainly still piled upon the floor. Shades of Grote and De Morgan who bequeathed their libraries to the university!

Sir Wm. Turner has been elected Principal of the Edinburgh University, and has told his class he will resign the Chair of Anatomy. The principalship will give him full scope for his remarkable energy and organizing talents, and he well deserves this highest honor the university can bestow. He may now, perhaps, resign the presidency of the General Medical Council.

Dr. Clouston has been elected president of the Royal College of Physicians of Edinburgh.

An appeal is about to be made for £20,000 to enlarge

and extend the work of the Edinburgh Students' Union.

A proposal to create an inferior grade of nurses for certain work-house duties under the name of "qualified nurse" has roused the rest of the nursing sisterhood, and the president of the Local Government Board is being bombarded with protests. It certainly seems absurd to use the word qualified for the very inferior class proposed. Many women interested in nursing are indignant at the proposal, but a considerable number of them should remember how they delighted to thrust an inferior order of midwives upon the public and profession.

LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE CHOLERA SITUATION IN THE PHILIPPINES—THE LEPER COLONY.

MANILA, December 1, 1902.
